List of Contributors

Yasmine Ali Abdelhamid mbbs, phd, fcicm, fracp
Intensive Care Specialist Physician
Intensive Care Unit
Royal Melbourne Hospital
Parkville, Victoria, Australia
Senior Lecturer and Senior Research Fellow
Department of Critical Care
Melbourne Medical School
The University of Melbourne
Melbourne, Victoria, Australia

Michelle Alisio MBBCh (WITS), FC Paeds (SA), DCH, MMed (UCT)
Senior Clinical Fellow
Department of Paediatric Intensive Care
Great Ormond Street Hospital
London, United Kingdom

James Richards Anstey MBBS, FRACP, FCICM
Consultant
Intensive Care Unit
Royal Melbourne Hospital
Parkville, Victoria, Australia

David Benjamin Antcliffe MB BS, PhD, MRCP, FFICM, EDIC
Senior Clinical Lecturer
Division of Anaesthetics
Pain Medicine and Intensive Care
Imperial College London
London, United Kingdom

Shabana Anwar MBBCh, BSC (Hons), MRCP, FRCA, FICM
Consultant Intensivist and Anaesthetist
Intensive Care Unit/Anaesthetics
Royal Brompton Hospital
London, United Kingdom

Sumesh Arora FCICM, MD, EDIC
Senior Staff Specialist
Department of Intensive Care Medicine
Prince of Wales Hospital
Sydney, New South Wales, Australia

C Jake Barlow MBBS, FANZCA, MPh
Fellow
Intensive Care Unit
The Royal Melbourne Hospital
Melbourne, Victoria, Australia

Nicholas A. Barrett MBBS(Hons), BSc(Med)(Hons), FANZCA, FCICM, PhD
Clinical Director
Department of Critical Care
Guy's and St Thomas' NHS Foundation Trust
London, United Kingdom
Honorary Senior Lecturer
Centre for Human and Applied Physiological Sciences
King's College London
London, United Kingdom

Paul B. Bartley BMedSc, MBBS (Hons 1), PhD, FRACP, FRCPA
Associate Professor
Department of Internal Medicine
University of Queensland - Uniting Care Health Clinical School
Auchenflower, Queensland, Australia
Infectious Diseases Physician
The Wesley Private Hospital
Auchenflower, Queensland, Australia

Sofina Begum MSc, MBChB, FRCSCTh
Consultant Thoracic Surgeon
Department of Thoracic Surgery
Royal Brompton Hospital
London, United Kingdom

Judith Bellapart MD, CICM, PhD
Senior Specialist Consultant
Department of Intensive Care
Royal Brisbane and Women's Hospital
Brisbane, Queensland, Australia

Rinaldo Bellomo MBBS, MD, FRACP, FCICM, PGDipEcho
*deceased
Director of Intensive Care Research
Department of Intensive Care
Austin Hospital, Melbourne, Victoria, Australia
Professor
Department of Epidemiology and Preventive Medicine
Monash University
Melbourne, Victoria, Australia

Andrew Bersten MBBS, MD
Professor Andrew D Bersten
Department of Critical Care Medicine
Flinders University
Adelaide, South Australia, Australia
Executive Director of Research
Southern Adelaide Local Health Network
Adelaide, South Australia, Australia

Rob Bevan MBBS, BMedSci, MRCP, FRACP, FCICM
Intensive Care Specialist
Department of Critical Care Medicine
Te Toka Tumai Auckland
Auckland, New Zealand

Shailesh Bihari MD, PhD, FCICM
Consultant
ICCU
Flinders Medical Centre
Bedford Park, South Australia, Australia
Professor
College of Medicine and Public Health
Flinders University
Bedford Park, South Australia, Australia

Alexander M. Bobinskas MBBS, FRACDS(OMS), FRCS(OMFS)
Consultant Surgeon
Department of Oral and Maxillofacial Surgery
Canberra Hospital
Garran, Australian Capital Territory, Australia

Scott Charles Borgna MBBS, BDSc, BPharm, FRACS(OMFS), RACDS(OMS)
Senior Staff Specialist
Department of Oral and Maxillofacial Surgery
Royal Brisbane and Women's Hospital
Brisbane, Queensland, Australia

Aimee Brame MBChB, FRCP, PhD, EDIC, FFICM
Consultant Intensivist
Department of Critical Care
Royal Brompton Hospital
London, United Kingdom

Katrina Bramley MBChB, BSc, MRCP(UK), FRCA, FFICM, EDIC, MSc
Consultant in Cardiothoracic Anaesthesia and Critical Care
Royal Brompton Hospital
London, United Kingdom

Alex Brown BMed, MPH, PhD
Professor of Indigenous Genomics
JCSMR

ANU
Canberra, Australian Capital Territory, Australia

Alex Browne BSc(Hons), BHB, MBChB, FCICM, FACEM
Senior Medical Officer
Department of Intensive Care
Te Whatu Ora o te Tau Ihu
Nelson, New Zealand

Angela Burgett FACEM, PEM, BSc (Med) MBBS, B Nursing (Merit)
Staff Specialist Emergency
Paediatric Emergency
Emergency Department
Robina Hospital
Southport, Queensland, Australia

Francisca Caetano MD
Consultant Anesthetist
Department of Critical Care
Royal Papworth Hospital NHS Foundation Trust
Cambridge, United Kingdom

Chris Callaghan PhD, FRCS
Consultant Transplant Surgeon
Department of Nephrology and Transplantation
Guy’s Hospital
London, United Kingdom
Honorary Reader
Centre for Nephrology
Urology
and Transplantation
King’s College London
London, United Kingdom

Sadie Callahan MBBS, FCICM
Intensivist
Mater Hospital
South Brisbane, Queensland, Australia

Alastair Craig Carr MB, ChB, MSc, DA FRCA, DICM, FFICM, FCICM, MBA
Clinical Director
Department of Intensive Care Medicine
Dunedin Public Hospital
Dunedin, Otago, New Zealand
Senior Clinical Lecturer
Department of Anaesthesia and Intensive Care Medicine
University of Otago
Dunedin, Otago, New Zealand

Sef Carter MBBS
Anaesthetics Core Trainee
Department of Anaesthesia
Theatres and Pain Medicine
Mid and South Essex NHS Foundation Trust
East of England School of Anaesthesia, United Kingdom

Binila Chacko I MD, DNB, FCICM, DM, FICCM
Professor and Head
Division of Critical Care
Christian Medical College
Vellore, Tamil Nadu, India

Marianne Chapman BMBS, FFARCSI, FANZCA, FCICM
Intensive Care Specialist
Intensive Care Unit
Royal Adelaide Hospital
Toorak Gardens, South Australia, Australia

Gordon YS Choi MBBS, FANZCA, FCICM, MHSM, FASE
Consultant and Deputy Chief of Service (ICU)
Department of Anaesthesia and Intensive Care
The Chinese University of Hong Kong
Hong Kong, China

Linsey Emma Christie MChB (Hons), BSc (Hons), MRCP, FRCA, FHEA, FFICM, MSc

Consultant in Intensive Care Medicine and Anaesthesia
Department of Anaesthesia
Critical Care and Pain
Chelsea and Westminster Hospital
London, United Kingdom

Andrea S. Christoff MD, FRACP, FCICM
Paediatric Intensivist
Department of Intensive Care Medicine
The Children's Hospital at Westmead
Westmead, New South Wales, Australia

Po Tong Chui MB BS, MHA, FANZCA, FHKCA
Honorary Associate Professor
Department of Anaesthesia and Intensive Care
The Chinese University of Hong Kong
Hong Kong, China

Christine Chung bachelor of pharmacy degree, msc in advanced pharmacy practice
Independent Prescriber
Lead Directorate Pharmacist
Imaging and Anaesthetics
Department of Pharmacy
Chelsea and Westminster NHS Foundation Trust
London, United Kingdom

Tina Anne Coco AO, RN, Dip.App.Science/N.Mngt., Masters-Organs Tissues & Cells
State Manager/Nursing Director
DonateLife Queensland
Princess Alexandra Hospital
Woolloongabba, Queensland, Australia

Jeremy Cohen BSc, MBBS, MRCP, FRCA, FCICM, PhD
Associate Professor
Intensive Care
Wesley Hospital

Brisbane, QLD
Associate Professor
Intensive Care
Royal Brisbane and Women’s Hospital
Brisbane, QLD
Honorary Professorial Fellow
The George Institute for Global Health, Adjunct Associate Professor
University of New South Wales

David J. Cooper BMBS, MD
Professor
Department of Intensive Care Medicine
Monash University
Melbourne, Victoria, Australia
Senior Intensive Care Physician
Intensive Care Unit
Alfred Hospital
Melbourne, Victoria, Australia

Carlos Corredor FRCA, FFICM
Consultant Cardiothoracic Anaesthesia and Critical Care
Department of Perioperative Medicine
St Bartholomew’s Hospital
London, United Kingdom

Julia Coull MBBS, FCICM
Intensive Care Specialist
Department of Intensive Care and Hyperbaric Medicine
The Alfred Hospital
Melbourne, Victoria, Australia
Adjunct Senior Lecturer
Faculty of Medicine
Nursing and Health Science
Monash University
Melbourne, Victoria, Australia

Alan Coulthard BMed Sci, MBBS, FRCSEd, FRCR, FRANZCR, GAICD

Senior Medical Officer
Department of Medical Imaging
Royal Brisbane and Women's Hospital
Herston, Queensland, Australia
Professor of Neuroradiology
University of Queensland
St Lucia, Queensland, Australia

Mark Graeme Coulthard MB, BS, PhD, FRACP, FCICM
Senior Staff Specialist (Retired)
Paediatric Intensive Care Unit
Queensland Children's Hospital
Casual Academic Tutor
Faculty of Health
Medicine and Behavioural Sciences
The University of Queensland
Brisbane, Queensland, Australia

Sarah Cox MBBS, FRCP, RCPathME
Consultant
Department of Palliative Medicine
Chelsea and Westminster NHS Hospital
London, United Kingdom

Nicholas WS Davies BSc, PhD, MBBS (Hons), FRCP
Consultant Neurologist
Department of Neurology
Chelsea and Westminster Hospital

Gold Coast University Hospital
Southport, Queensland, Australia

Preface

Oh’s Intensive Care Manual , first edition, was published in 1979, when intensive care may not have been in its infancy, but it certainly was not far beyond. Teik Oh, with tremendous foresight, brought together the fundamental elements of managing the critically ill in a particularly pragmatic manner, which could be considered a guideline for the development of the speciality. Forty-six years on, we are pleased to present the ninth edition, which reflects both the maturation of the speciality and the phenomenal progress medically, technologically, scientifically, ethically and educationally in all areas of management of critically ill adults and children.

The entire content of this edition has been reviewed and updated to reflect the changing nature of the speciality and the subtle shifts in emphasis in the workplace. Numerous new authors from around the globe have joined the contributor list, bringing their own expertise and a fresh look at updated chapters.

This edition contains new sections on Decision Making, Special Populations and The Post-Operative Patient and includes numerous new chapters, including Allied Health Professionals in ICU; Clinical Assessment of the Critically Ill Patient; Determination of Death in ICU; Mechanical Cardiac Supports; Acute Aortic Syndrome; Overview of Respiratory Failure in ICU; COVID-19; Neuromonitoring; Pre-Operative Assessment of the High-Risk Patient; Post-Operative Thoracic Surgical Patient; Post-Operative Neuro-Surgical Patient; Principles of Organ Procurement and Donation.

As before, we hope that this edition will achieve several goals. It will incorporate changes to reflect the changing knowledge base of our profession; it will address emerging issues in intensive care; it will be of use to medical, nursing and allied health staff and students; but most importantly, it will adhere to the pragmatic and clinically useful style so effectively promulgated by Teik Oh.

We are deeply indebted to many people whose efforts have resulted in this book. First, the authors who have produced the most up-to-date chapters incorporating the latest scientific evidence in the field and maintaining the clinical focus. Second, this book has also been informed by discussions over the years with trainees, trainers, examiners and colleagues who have emphasised the importance of maintaining Oh's manual as the essential reading material for examinations. This book would not have been possible without the outstanding support, contribution and hawk-eye scrutiny from our deputy editors, Associate Professor Jeremy Cohen and Professor Daniel Martin, who joined the team during the preparation of this new edition. Finally, we would like to thank the staff of Elsevier for their excellent assistance in the production of this book.

We are privileged to have compiled the ninth edition and feel that if a clinician can reach for it in the early hours of the morning and can easily locate the information they require and feel either guided or reassured, it will have served its purpose. If those passing examinations can say it helped, that will be the crowning glory.

Jonathan M. Handy
Bala Venkatesh

Acknowledgements

The publication of this book is a testament to all who have contributed, and we hope that the end product honours the spirit and reputation of editions that have gone before. We, the editors, are indebted to those who have given up significant time to impart their expert knowledge and experience through the words contained within. While we are excited to see this new edition reach fruition, the untimely death of three friends and contributors has brought sadness and reflection. Michael Houston (Executive Content Strategist at Elsevier) was the driving force behind this new edition; without his commitment, it may have never been conceived. We mourn too the loss of Professor Rinaldo Bellomo and Dr Kevin McCaffery, whose chapters will allow us to benefit from their wisdom for years to come. It seems fitting to reflect on the true beneficiaries of this book over the years; not only the clinicians who have accessed the knowledge within, but the countless patients for whom they have cared and whose care will have been enhanced through the sharing of expertise by our contributors, both past and present.

Design and organisation of intensive care units

Peter Kruger and Nhi Nguyen

What is an ICU

Intensive care units (ICUs) developed from the postoperative recovery rooms and respiratory units of the mid-20th century, when it became clear that concentrating the sickest patients in one area was beneficial. The ICU is a separate and self-contained area within a hospital for the care of patients with life-threatening or potentially life-threatening and reversible or potentially reversible organ failure. The ICU provides a concentration of clinical expertise, technology and therapeutic resources for the support of patients and their families, and utilises the specialised skills of medical, nursing and other staff experienced in the management of critically ill patients. [1] These skills and resources, necessary to care for the critically ill, are most efficiently concentrated in one area of the hospital.

The clinical service provided by the ICU reflects the needs of the hospital and health service district. Hence there exists some variability in the size and models of care across rural, regional, metropolitan and tertiary centres. Fundamentally, the ICU provides care for patients who cannot be managed in a standard ward environment within a particular hospital. Consideration of the staffing and skill mix across the remainder of the hospital means that the criteria for ICU admission will vary across hospitals and health service districts. Considered to be both necessary and the most efficient as each hospital provides the highest quality care for their most unwell patients within their unique environment.

In all clinical environments, the skills of the intensive care team are required 24 hours a day, 7 days a week. Patients admitted to the unit may be planned or unplanned and can come from operating theatres, emergency departments, wards and other areas of the hospital. Patients may also be transferred from different facilities via retrieval services. The unpredictability of admissions means that staffing needs to be organised in such a way that there can be some agility and responsiveness to the needs, irrespective of the time of day or day of the week.

Across all health systems, there are varying models for the provision of a higher level of monitoring or interventions. Historically hospitals were organised with medical and surgical ICUs and high-dependency units (HDUs) scattered across the hospital. In efforts to standardise models of care and governance, increasingly ICUs have a broad mix of patients (general) rather than disparate smaller specialty pods. Large tertiary centres may have sufficient case mix and case load to organise some pods into subspecialties such as neurosurgical or cardiac. The separate subspeciality ICU models still exist in many countries across the world. [2] In general terms, units are designated adult, paediatric or neonatal. The units which admit both adults and paediatric patients (mixed units) are a minority and often in smaller regional centres.

There are various ways to classify ICUs. [3-5] These frameworks all allow for an understanding of the services able to be provided by a particular ICU. The clear delineation of the capability of the unit is important to allow planning for other services delivered at the hospital (complexity of surgery as an example). It also outlines what services are required for the delivery of intensive care, such as 24-hour pathology and radiology services, as well as the equipment and the staffing skill mix to best facilitate clinical care. These frameworks highlight the important symbiotic relationship that exists between each hospital and its ICU activity. Provision of intensive care is a specialised and expensive resource, and governing and funding bodies must balance service needs and available resources.

There are various ways to describe the levels of care provided to patients when considering the complexity of the patient and their nursing dependency. In many regions, ICU represents the highest level, with many hospitals having some intermediate level that is advanced from general ward care. These intermediate levels are referred to by varying terms such as high dependency, high acuity, level 2 care or close observation units depending on the region. In some cases, they may also serve as an ICU step-down area to provide a level of care between the ICU and the ward.

These intermediate acuity areas, whatever they are called, may be both functionally and administratively incorporated within the ICU. Separate specialised guidelines should exist for staffing, structure and function of these units whether they are stand-alone units or incorporated into the ICU. [6] Organisation of units which allow for the flexibility in nursing to patient requirements (1:1, 1:2) affords some operational efficiencies. Although, patients cared for in an ICU would usually need 1:1 nursing, this is not always the case. In times of crisis, such as seen during the COVID-19 pandemic, these usual staffing ratios needed to be stretched further. In hospitals without a dedicated HDU, the ICU maybe the most appropriate place for some patients who require closer monitoring to be managed. In planning for mixed ICU/HDU areas, it should be noted that less critically unwell patients require facilities such as additional bathroom facilities and may have different physiotherapy requirements. The arrangement of such units should address the variable needs of patients as they transition through the stages of their critical illness and some consideration of the potential psychological issues of having more awake patients in a busy ICU environment. Other higher acuity areas, such as close observation units, may exist in some hospitals, but these usually do not fulfil the requirements or role of true HDUs.

Principles of design of the ICU

Appropriate Planning and Capacity

Intensive care accounts for a significant component of overall hospital resources. There is significant variability in the number of ICU beds per 100,000 population across jurisdictions and countries across the world. [7-9] While exact numbers vary, some examples include 3.6 per 100,000 population in New Zealand up to 25.8 per 100,000 in the United States. [10] The determination of the appropriate number of ICU beds a hospital or area needs should be based on all available data. These data should include information such as historical bed utilisation, demographics of the patient cohorts, levels of organ support and degree of exit block (where patients are awaiting a step down or ward bed), to allow for future projections. ICU medical and nursing staff should always be involved in the ICU design and selection of fixtures and equipment that support their ability to provide care for critically ill patients.

Depending on the number of beds to be provided, they can be organised in pods. The optimal size of the pods needs careful consideration, balancing the service needs with the ability to organise staffing on a day-to-day basis. Ten to fourteen beds are considered the maximal pod size which one senior intensive care clinician can oversee.[5,11] Units with more than one pod will usually organise their medical staff into teams being responsible for each pod.

ICU Location and Layout

A high standard of intensive care medicine is influenced by its location and relationship with the rest of the hospital as well as good design and adequate space. Whenever renovations or new structures are being planned all these aspects need to be considered. A safe and efficient workplace is an absolute requirement and is best achieved during the design phase by finding ways to eliminate hazards and minimise risks. Effective design will consider all aspects of both workflow and physical environment and the interactions of everyone in the workspace.[12-14]

The location of the ICU within the hospital should ideally facilitate access from the emergency department and operating theatres and a close relationship with imaging facilities (and interventional radiology if available). Security and hazard management both work better when incorporated by design. Back-of-house activities such as stock delivery and waste removal would ideally have an entry into the unit which is different from the main patient and visitor access. A reception area for visitors with an appropriately sized waiting room should be provided. Information for visitors can be provided in this space. How entry and visitation are to be managed within hours and after hours needs to be considered both from a design and operational perspective. Likely travel paths for the transport of critically ill patients should be mapped out carefully to ensure that there are lifts large enough to accommodate the patient bed, equipment and staff. Entry doors should ideally be automatic with staff swipe accessibility and lifts must have emergency override functionality.

Over the last 20 years, there has been a shift away from central stations with a clear view of surrounding open bays to a higher proportion of single/enclosed rooms.[15] The aim was to provide a quieter environment, increased privacy for patients and an improvement in infection prevention and control measures. This may have come at a cost, as staff report feeling more isolated with poorer communication between staff, and the reduced line of sight makes cover for nursing breaks more difficult, with the result that increased staff numbers are required.[16,17]

Increasingly, ICUs are designed with a long axis to provide maximal access to natural light in all clinical areas. This is believed to be important to decrease delirium and optimise sleep patterns.[18,19] Natural light is also important for staff well-being. Unintended consequences of these designs may be an increase in reported adverse events and the use of more sedation. The design of an ICU should balance what are often competing goals and should incorporate mitigation of perceived risks such as increasing the number of staff to provide support or the use of remote monitoring systems.[16,20]

ICUs need to have an appropriate number of negative pressure rooms. The ideal number is a balance between anticipated clinical needs, the cost associated with construction and the ongoing maintenance required for these rooms. Ante-rooms, which are needed to deliver negative pressure in the patient room can also be used for donning and doffing. Providing more negative pressure rooms than required for normal circumstances not only uses up significant clinical areas, but it can also restrict access to the patient area when the room is required for non-infectious patients. During the COVID-19 pandemic, many more negative pressure rooms were required than were available in most ICUs.[21,22] Some unit designs allowed entire pods, or in some cases even the entire ICU, to be converted into an appropriate isolation environment. A review of air circulation and secure access to isolate larger areas than a single bed space may prove to be an effective option to adapt clinical spaces during larger-scale outbreaks of infectious diseases and still maintain the functionality of the ICU at other times. Positive pressure rooms are only provided where specialised services such as organ transplantation are provided by the hospital.

Health facility guidelines provide details on total areas, bathroom requirements and other suggested amenities.[11,14] In addition to family waiting rooms, smaller spaces for private reflection and discussions are also required. Outdoor balconies that have appropriate gas and electrical supplies to support patient care can add significantly, particularly for longer-stay ICU patients.

The Patient Zone: Each Bed Space or Bay

The design principles should have both flexibility and function in mind. Each bed space should be a minimum of 20 m^2 and ideally 25 m^2 regardless of adult or paediatric use. There should be adequate circulation space around the bed, with a clearance of at least 1.2 m at the head and foot of the bed.[4,11,14] There should be adequate space on either side of the bed for equipment, caregivers and family. There is a case for the provision of a few bed areas which are bigger than standard sizes for the management of patients requiring more complex organ support such as extracorporeal membrane oxygenation (ECMO). All doorways in clinical areas should be at least 1200 mm wide and often wider to allow equipment and staff-ready access.

There has been an increase in the utilisation of switchable glass (where windows can be made opaque in lieu of curtains) in single rooms. The decision to use this technology is a balance between the available budget, ongoing maintenance, the cost of replacing curtains as well as infection control principles.

Debate continues regarding the merits of single rooms versus bed spaces combined as ‘bays’. It may be that some mix of both provides a balance for privacy, the flexibility of staffing and the potential for improved infectious isolation or other clinical benefits.[23] Bay designs can use either solid sliding panels or curtains to create the bed space separation. Sliding doors between single rooms can provide ease of access for staff to care for patients in adjacent rooms, without compromising privacy and the benefits. All rooms and bays must have handwashing sinks, ideally automated or foot operated, with conveniently located antiseptic gel receptacles.

Pendants have become standard in most new fit outs, often at both head and foot ends. The provision of ceiling-mounted pendants removes clutter from the floor as equipment and monitors can be secured on the pendant. As the gas and electrical outlets are on the pendant arms, there is also the flexibility to move patients around the room as needed for procedures as well as rotating the orientation of the bed such that patients can face internally or externally to the window. Some considerations for hoists for lifting and bariatric capacity are increasingly important. Methods to orientate patients to time, date and place are required and consideration of additional space to display personalised images (pictures, cards and drawings) may improve the patient and family's experience.

Cardiac electrical protection is required in all clinical areas, and each bed space should include at least 16 general power outlets (GPOs), gas and air outlets as well as three suction outlets. Emergency power must be available on at least some of these GPOs for essential equipment when there is a disruption in the main power supply. Data outlets need to accompany the GPO as increasingly automatic feeds to monitors and electronic medical records become the norm.[4, 11] Engineering requirements related to the appropriate number of air exchanges per minute are well described in relevant building standards. Anteroom access and clean versus dirty staff change facilities have all become more prominent since the COVID-19 pandemic highlighted their importance. The ICU should not only have adequate air circulation, but it should also be climate controlled to optimise patient and staff comfort.

In addition to the physical layout of the ICU, the choice of surface material and furnishings is important. They need to be easy to clean and disinfect and be durable, but this can also influence noise levels.[24] Rooms should have large windows with good access to natural light allowing the patient bed to be orientated to face the window. Lighting can also be controlled with different types of artificial light, screens with images that change with day and night cycles or window coverings to balance natural light. Graphics may improve the patient experience, particularly for children. If using Venetian blinds, these should be integrated between glass panels for cleaning purposes.

The importance of communication from isolation rooms was highlighted during the COVID-19 pandemic. It became clear that electronic communication from inside isolation rooms to other staff was extremely helpful in planning clinical care, medication restocking and highlighting concerns. Some devices were ineffective when using personal protective equipment (PPE) and a no-touch requirement had huge advantages over devices that required a specific hand-to-button for activation. Voice activation often proved more difficult in full PPE. Video features and ‘hard-wired’ rather than retrofitted wireless options may offer additional benefits.

Clinical Support Areas

Although the patient care areas are the central focus of any ICU, the clinical support areas are vital. The total area of the ICU should be two to three times the patient care area, highlighting the varied and important roles these spaces provide. Some storage and support space should be located within close proximity to the patient care area to provide ready access to staff or equipment in an emergency. As a guide, a unit will likely require at least 10 m^2 of storage per bed space, although some of this space may be more remote to the clinical area. For larger ICUs, because of the physical footprint constraints, some of the clinical support areas cannot be adjacent to the clinical areas. In these circumstances, prioritising facilities such as staff change rooms and break rooms nearby is important such that staff can easily access these areas during their meal breaks. These areas should have annunciators installed for emergency responses within the ICU.

The staff facilities required will be related to the number of ICU beds, and this should be an integral part of the planning of any new build or ICU expansion to ensure appropriate clinical and staff support facilities exist. Areas for staff rest may include separate sleeping facilities for on-call or overnight staff.

Depending on the proximity of pathology laboratories in the hospital, many ICUs have a space for point-of-care testing such as blood gas analysis or thromboelastography. Consideration should be given to pathology and pharmacy transport, with pneumatic tube systems being one solution. Separate clean and dirty utility areas are required. Dedicated equipment storage areas will avoid cluttered corridors and allow ready access when required. Specific space and staff are required for appropriate equipment maintenance, and in some cases, this may be away from the main ICU footprint. Medication storage is often in dedicated rooms with secure access that meets specific local requirements. This secure access may have either video or secured access to allow a review of entry to these areas if required.

Spaces for education require dedicated and appropriately sized meeting rooms with facilities for audiovisual and IT support to ensure online as well as in-person participation. Simulation spaces should be available, and these may be either dedicated purpose-built facilities or lower-fidelity areas making use of locally available spaces, ideally within the ICU. Although library spaces no longer require large areas for physical storage, as many resources are digital, some space will still be required for equipment and any local resources used for teaching and study.

Office space will be required for a variety of ICU staff, including the ICU medical and nursing leadership team, senior and junior medical staff, those with senior clinical nursing portfolios as well as education, data managers, research staff, social work, administrative support staff, operational officers and the variety of allied health specialities that are part of the ICU team. While shared spaces may work for some of these roles, careful consideration will be required around the privacy and efficiency loss that may come with this. When large communal spaces are being considered additional break-out spaces for small group meetings or private discussions will be required. Dedicated desk spaces for staff usually work better than ‘hot desk’ arrangements that require those in clinical support roles to pack up completely at the end of each shift. Specific guidelines exist [25] that suggest the layout of work areas should be designed to provide sufficient clear space between furniture, fixtures and fittings so that workers can move about freely without strain or injury and also evacuate quickly in case of an emergency.

When determining how much office space is needed the design should consider any physical actions needed to perform work tasks, the need to move around while working and whether the task is to be performed from a sitting or standing position. Both access to and space around any workstation as well as space for aisles, passages and access to other areas are needed. [25] These guidelines would apply equally to offices as well as other clinical support work areas within the ICU.

Information Technology in the ICU

The computer and information technology requirements for a modern ICU warrant specific and separate consideration. Many ICUs have provisions for telehealth, as this may facilitate support between smaller and larger ICUs and hospitals.

Although clinical information systems are not yet universal, they are increasingly common and most newly built ICUs would at least plan for this eventuality at the design phase. These systems not only require additional power and data capacity but also increased physical space. Combinations of fixed and mobile workstations are needed for the bedside nurse as well as for team members attending the patient intermittently throughout the day. Mobile workstations will require specific storage and charging bays.

The design of the ICU can influence the locations of computer keyboards and screens in bed spaces. To limit clutter around bed spaces, dedicated alcoves for computers are sometimes used for single rooms. These may be inside or outside the room with each approach having both advantages and disadvantages. [20]

When considering patient safety in medication handling, prescribing permissions should be carefully considered. Hospital-wide clinical information systems make this a challenge, which may mean this restriction is not possible. This comes with the significant risk that staff outside the ICU can adjust medication prescriptions without the ICU medical team’s input.

Teleconferencing facilities should be readily available to enable telehealth support of regional centres as well as for the conduct of multidisciplinary team meetings. This proved vital during pandemic periods when there were limitations to the number of staff congregating in small rooms.

Specific consideration should be given to communication requirements within the ICU as this may require Wi-Fi–enabled landlines, mobile phones or internal Wi-Fi networks. Although mobile phone use by patients or family may have advantages, such as facilitating communication with family and friends and ready access to health information available on hospital or other networks, it can also raise privacy concerns, particularly around photography and video recordings. In addition, interference with some medical equipment is possible if in close range. Each ICU should develop a specific policy and approach that works for their patients, family and staff.

Organisational considerations

Staffing

The provision of intensive care involves a dedicated multidisciplinary team. It is crucial that there is clear and proper communication and collaboration among team members and a truly multidisciplinary approach. Knaus et al. [26] in a classic study first showed the importance of the relationship between the degree of coordination in an ICU and the effectiveness of its care. Other studies have shown relationships between collaboration and teamwork and better outcomes for patients and staff. [27]

Increasingly the delivery of health care services may require larger hospitals to support smaller facilities. This is often done through telehealth or virtually. Supporting staff in these facilities helps to keep patients closer to home and should be resourced appropriately. [2]

Medical Staff

A department of intensive care should have an appropriately qualified specialist as a medical director who coordinates the clinical and administrative activities of the department. The director should have oversight of patient care, supervision of staff, the diagnostic and therapeutic protocols and the quality, safety, research and education activities of the department. This should be done in concert with the nursing leadership team and other appropriate department and hospital staff. It is recommended that the director have a significant presence in the department.

The financial management of the ICU is increasingly done by the medical and nursing leadership team in concert with appropriate hospital executives with business and finance expertise. These are often multimillion-dollar budgets or even greater in large tertiary ICUs.

There must be a specialist (Consultant in Intensive Care Medicine) exclusively rostered to the unit and a junior doctor with an appropriate level of experience present in the unit at all times.[4,5] The department should have sufficient numbers of staff to allow reasonable working hours, protected non-clinical time and leave of all types.

Participation in activities outside of the ICU, such as attending a deteriorating patient and accompanying the medical emergency response team, has increased the workload of all intensive care staff and these activities must be appropriately resourced to allow the ICU itself to continue to function safely at all times.

Medical work patterns are important for providing high-quality care for patients and staff. These patterns include the nature of rosters that limit fatigue, enforce adequate breaks and time off and the structure of handover and daily rounds.[28] Professional or government organisations provide guidelines and benchmarking reports about safe working hours, on-call arrangements and assessment tools to facilitate better rostering.[29]

Nursing Staff

In well-established health systems, there are published standards that reflect the central role of the bedside nurse and how appropriate support for staff contributes to the care of the critically ill.[5,30-32] Standards highlight appropriate training and skill mix, ratios including ACCESS nurses, ongoing educational support and the vital role of the non-nursing staff in the ICU. Additional roles will need to be factored into the total establishment of critical care unit staffing to support roles such as outreach, research, quality improvement, rapid response teams, patient retrieval and transport, teaching of critical care courses, equipment nurses or technicians and practice development.

An ICU should have a nurse manager who is appointed with authority and responsibility for the appropriateness of nursing care and who has extensive experience in intensive care nursing, as well as managerial experience. In larger units the nurse unit manager will be supported by other clinical nurse specialists with specific responsibilities such as education, rostering, equipment, quality assurance and others. These specialised roles, together with the senior medical staff, form the ICU leadership team. Ideally, there should be regular, combined multidisciplinary leadership meetings.

Allied Health Professionals

Access to ICU-specific physiotherapists, dietitians, speech pathologists, occupational therapists, psychologists, social workers and other therapists should be available. A dedicated ward clinical pharmacist is invaluable, and participation of a pharmacist on ward rounds has been associated with a reduction in adverse drug events.[33], [34] Respiratory therapists are allied health personnel trained in and responsible for the equipment and clinical aspects of respiratory therapy, a concept well established in North America but not the UK, continental Europe and Australasia. Technical support team members, either members of the ICU staff or seconded from biomedical departments, are necessary to service and repair equipment.

Support Staff

Provision should be made for adequate administrative and operational support. Administrative support includes both clinical and non-clinical support functions and this may involve different teams depending on the size of the ICU. Operational staff will also have roles that support clinical care (turning and lifting patients for procedures or pressure area care, patient transport) and clinical support roles such as cleaning, maintenance and in some cases, security staff. As with other members of the ICU team, regular staff who are familiar with the ICU environment and requirements results in improved workflow, teamwork and likely patient outcomes.

There should also be a point of contact for local interpreters, chaplains, priests or officials of all beliefs when there is a need for their services.

Operational Policies

Well-defined policies are vital to the functioning of an ICU. There must be clearly defined policies for admission, discharge, management and referral of patients. A *closed collaborative model* for ICU is preferred where all patients are primarily under the care of the treating ICU specialist. Close collaboration with a patient's primary specialist and any other appropriate specialty units is vital. An open ICU model is one where the treating clinician determines admission/discharge and day-to-day management of the patient within the ICU. An intensive care specialist is not responsible for the coordination or delivery of care. This model continues in selected regions, particularly North America, and the merits continue to be debated.[35-37]

Regardless of the operational model, coordinated management, consistent good communication (with staff, patients and families) and collaboration with all members of the healthcare team remain central to ensure optimal care.

All ICUs will require policies, guidelines and protocols. These will variously describe the different aspects of the care of patients and should be unambiguous, periodically reviewed, familiar and readily available to all staff. When they involve complex clinical issues (such as weaning from mechanical ventilation), they might be less effective than the judgement of experienced clinicians.

Care of Patients and Their Families

ICU patient management should be multidisciplinary, with medical, nursing and other staff working together to provide the best care for each patient. The patient should be assessed by a formal ward round at least twice daily. The bedside nurse and the nurse coordinating the floor, pharmacists, dietitians and other allied health specialists should have the opportunity to be involved in daily patient rounds. Each patient should be assessed clinically (examination, observations and pathology, radiological and other investigation results), the medication chart reviewed, progress determined and a management plan developed for the immediate and longer term.

Unstable patients are likely to require much more frequent assessment and intervention than those who are more stable.

It is crucial that all observations, examination findings, investigations, medical orders, management plans (including treatment limitations) and important communications with other medical teams and patients' families are clearly documented in the appropriate chart or part of the medical record either electronically or in writing.

Family as well as patient-centred care is a core part of ICU practice. It is important that there are early and repeated discussions with patients' families to reduce family stress and improve consistency in communication. Discussions should be interactive and honest, especially with respect to outcomes and potential complications. Cultural factors should be acknowledged and spiritual support available. Open visiting hours allow families maximum contact with their loved ones and promote an atmosphere of openness and transparency.

Non-Clinical Activities

Activities that support clinical care in the ICU are vital. They enhance safety, quality and improve the evidence base for patient care.

Quality Improvement

The three key pillars of quality improvement are audit, incident monitoring and data review. Every ICU should maintain a database that is sufficiently well structured to allow easy extraction and reporting for benchmarking, quality control and audit. Staff members who collect and process the data should have dedicated time to perform these roles.

All ICUs should have demonstrable and documented formal audits and reviews of their processes and outcomes in a regular multidisciplinary forum. The traditional mortality review meetings have expanded to include morbidity (M&M). A regular structured review around morbidity, the 'little m' component of these meetings, can provide enormous opportunities for quality improvements. Quality assurance programs should also include patient-reported experience measures (PREMs) and patient-reported outcome measures (PROMs) as these provide valuable insights into care experienced by patients. [38]

The three types of quality indicators relate to [39] :

Structure : These indicators assess whether the ICU functions according to its operational guidelines and conform to the policies of training and specialist bodies (e.g. clinical workload and case mix, admission and discharge capacity and staffing establishment)

Clinical processes : These indicators assess the way care is delivered such as whether deep vein thrombosis prophylaxis is given or time to administration of antibiotics in patients with sepsis.

Outcomes : Examples of outcome measures may include survival rate, quality of life of survivors and patient satisfaction. Family satisfaction may provide additional insights and is vital in paediatric units.

Education

All ICUs should have a documented orientation programme for new staff. There should be formal specific ongoing educational programs for medical and nursing staff and ideally be multidisciplinary. Meetings to review newly published evidence relevant to practice should be held regularly. Regular assessments for advanced life support and sometimes other assessments (e.g. medication safety) are often required. Increasingly, simulation centres are used to teach and assess skills and teamwork in crisis scenarios. These should be multidisciplinary to replicate the teamwork required in delivering clinical care in the ICU. Some ICUs are also involved in undergraduate medical, nursing or allied health teaching. ICUs involved in the training of medical specialists are accredited at regular intervals by the responsible college or faculty bodies using specific guidelines that often cover all aspects of physical infrastructure, organisational arrangements, supervision, teaching and clinical care.

Research

Irrespective of size, all units should attempt to undertake some research projects whether these are unit based or contributions to multicenter trials.

In larger teaching hospitals, ICUs may be able to develop sophisticated research programs with dedicated research coordinators and other medical, nursing and allied health staff involved.

Staff Well-Being

While much is made of the physical structure and environment of an ICU, the thing that defines these units is their people. The staff who work in the ICU are a precious resource and specific attention to their welfare and well-being should be part of 'business as usual' for any hospital service. The physical environment of the unit and the organisation of rostering, leave and education are all fundamental in approaching staff well-being. An active approach to ICU culture is crucial to the well-being of everyone who interacts with ICUs.

Rapid response systems: care of critically ill patients outside of critical care

John Robert Welch and Christian Peter Subbe

Key Principles Include

- Deteriorating patients can be identified by careful monitoring of physiological signs – understanding that many hospital patients are in their last year of life.
- Timely escalation to critical care should improve outcomes.
- Effective responses to acute deterioration are often hindered by human factors.
- Rapid response systems standardise the response to at-risk and deteriorating patients and improve process and clinical outcomes for such patients.
- Better outcomes result from multiprofessional working and effective communication, education, data collection/audit, learning from errors and the planned improvement of whole systems of care.

Background

Services to support deteriorating patients outside of intensive care have been developed in countries around the globe against a backdrop of changes in the epidemiology of patients admitted to hospitals, the functioning of clinical teams and a greater focus on the safety of care.

Patients admitted to the hospital are older, frailer and present with more complex conditions, while there is pressure for a shorter length of hospital stay than in previous decades. Independent of the health care system, intensive care units (ICUs) have a limited number of beds and often high rates of occupancy. Consequently, many high-risk patients remain in areas with staff inexperienced in managing critical illness. Key tasks, such as measuring vital signs, are often delegated to untrained personnel who may not understand the significance of abnormal values. Junior doctors might be underprepared for emergency management of patients with multiple complex co-morbidities, multidisciplinary teamwork, handover and other safety-critical tasks.[1] In addition, many hospitals use temporary staff who are less likely to provide the continuity and teamwork essential for effective care.

Comparisons of outcomes of patients admitted to an ICU from either the emergency department, operating theatre/recovery area, or wards show that those coming from wards have the highest mortality.[2] Suboptimal treatment is common before transfer to the ICU,[3–5] and is associated with worse outcomes.[3],[4],[6] An analysis of hospital deaths in a national database found that ‘*the most common incident types were failure to act on or recognise deterioration*’.[7] Crucially, differences in mortality might be attributable to variations in care rather than differences between the patients themselves.[6] Patients experiencing long periods of instability before there is an effective medical response are said to have suffered ‘failure to rescue’. Such failures are common: in a national review of patients subsequently transferred to the ICU, many had sustained up to 72 hours of physiological instability.[3] Indeed, a review of 1000 deaths in 10 hospitals in the United Kingdom concluded that 52 of these deaths would have had a 50% or greater chance of being prevented, although it is noteworthy that most of these were in elderly, frail patients judged to have a life expectancy of less than a year.[8] Other patients at risk are those recently discharged from the operating room after major surgery or from the ICU; about one-quarter of all ‘intensive care deaths’ occur after transfer back to the ward.

Failures to rescue can be divided into failure to record safety-critical vital signs, failure to recognise, failure to report, failure to respond and failure to continuously repeat the monitoring process.[9]

Critical care outreach, medical emergency and rapid response teams

The concept of critical care outreach teams (CCOTs), rapid response teams (RRTs) or medical emergency teams (METs) providing ‘*critical care without walls*’[10] originated in Australia, spread to the United Kingdom and has become a standard of care across North America and many European countries. It is now also deployed in the Middle East,[11] Far East[12] and Central and South America[13] while being mandated by law in regions as different as Japan and the Netherlands. The aim is ‘*equity of care for all critically ill patients irrespective of their location*[14].’

METs were first introduced in Australia in the 1990s, usually comprising critical care residents and medical registrars. These teams could be directly activated by any member of staff, bypassing traditional hospital hierarchies. METs expanded the role of the cardiac arrest team to include the pre-arrest period, generally using call-out criteria based on deranged physiological values or staff concerns.[15] In the United Kingdom, a review of critical care services in 2000[16] led to increased funding and the creation of CCOTs largely staffed by critical care nurses. Similar services then appeared in Canada, the Netherlands, New Zealand and the United States, driven by the Institute for Healthcare Improvement[17] with an emphasis on a complete ‘rapid response system’ (RRS). This highlighted the principle that whole, coordinated systems are needed to reliably avoid failure to rescue.

The RRS can be divided into:

- an afferent component designed to ensure the timely escalation of the deteriorating patient – usually using agreed physiological values as a trigger for activation of a response – the efferent component

- an efferent component comprising an individual or team of clinicians who can rapidly respond to deterioration
- audit, governance and administrative structures to oversee and organise the service and its ways of working.

The terminology for the description of RRSs is not standardised, but METs are usually physician-led, while CCOTs and RRTs are typically nurse-led, but may include other allied health professionals as well as doctors. Most teams respond to calls from staff on wards after defined physiological triggers have been breached, although some also work proactively, regularly reviewing known at-risk patients, such as those discharged from the ICU. The objectives of an RRS are to reduce preventable critical care admissions, to ensure timely transfer to the ICU when needed, to facilitate safe return to the ward, to share critical care skills [16] and to improve communication and knowledge about acute deterioration throughout the hospital. Some teams additionally support patients and their families after hospital discharge (Box 2.1).

Box 2.1

Functions of critical care outreach

- Identification of at-risk patients.
- Support for ward staff caring for at-risk patients and those recovering from critical illness.
- Referral pathways for obtaining timely, effective critical care treatments.
- Immediate availability of expert critical care and resuscitation skills when required.
- Facilitation of timely transfer to a critical care facility when needed.
- Education of ward staff in recognition of fundamental signs of deterioration and in understanding how to obtain appropriate help promptly.

- Outpatient support for patients and their families following discharge from the hospital.
- Development of systems of coordinated, collaborative, continuous care for critically ill and recovering patients across the hospital and in the community.
- Audit and improvement of basic standards of acute and critical care – and of the outreach team itself – to minimise risk and optimise treatment of the critically ill throughout the hospital.

Together, these elements comprise a system to deliver safe, quality care with proactive management of risk and timely treatment of critical illness.

RRSs have highlighted shortcomings in the care of ward patients and contributed to a significant change in attitude towards patients at risk. They have been instrumental in improving ward monitoring and in disseminating critical care skills. There are anecdotal reports of benefit to individuals, [18] and growing evidence of improved recognition of at-risk patients; with reduced length of stay, cardiac arrests, unplanned admissions to critical care and morbidity and mortality. [19–22] Positive reports include a randomised trial of the phased introduction of a 24-hour outreach service to 16 wards in a general acute hospital in the United Kingdom. [23], [24] The outreach team routinely followed up patients discharged from intensive care to wards and saw referrals generated by ward staff concern or the use of an early warning score (EWS). There was a statistically significant reduction in mortality in wards where the service was operational. In contrast, a large prospective, randomised trial of METs in Australia found no improvements in cardiac arrests, unplanned admissions to the ICU or unexpected deaths in comparison to control hospitals in the primary analysis. [25] However, a secondary analysis showed improved outcomes in most hospitals in both the intervention and control groups, with dramatic improvements in those with the weakest baseline performance. [26] This study revealed shortcomings in the identification and care of critically ill patients, with one possible conclusion being that it is essential to take whole systems approach to achieve timely recognition and response and that it takes time to affect significant change across the entire hospital. An interrupted time series study of nearly 10 million patients in 232 hospitals described a progressive reduction in failure to rescue, cardiac arrests and mortality from early on, but better outcomes for the low-mortality diagnostic-related group of patients only in the later years. [27,28]

Several studies have shown an inverse relation between the number of calls to the RRS and cardiac arrests (‘MET dose’). [29] This may reflect better patient assessment, more timely implementation of Do-Not-Attempt-Resuscitation orders, and the involvement of palliative care specialists in patients with terminal illnesses. This is not a negative: the delivery of good palliative care can be seen as a positive outcome reinforced by an RRS. [30]

There have been fewer investigations of the follow-up of patients discharged from the ICU, although this group is known to be at significant risk. A matched-cohort analysis of 5924 patients found that follow-up by an outreach team reduced length of stay and mortality compared to historical controls and matched patients from hospitals with no outreach. [31]

The Afferent Limb: Recognising the Critical Illness

Patients with potential or actual critical illness can be identified by a review of their history, by examination and by investigations. Higher risks are associated with frailty, significant co-morbidities, or some presenting conditions, such as pancreatitis or sepsis.

A consensus conference on the afferent limb of the RRS reported that (1) vital sign aberrations predict risk; (2) monitoring patients more effectively may improve outcomes, although some risk is random; (3) the workload implications of monitoring should be investigated; and (4) ideal monitoring systems for different levels of care, from general ward to the ICU can be described with detail of the methods of data acquisition and monitoring frequency. This enables the categorisation, comparison and appraisal of systems. [32]

There is a known association between abnormal physiology and adverse outcomes. [33,34] Critical care scoring systems, such as APACHE II, [35] are based upon this relationship. Patients who suffer cardiac arrest [36] or who die in the hospital generally have abnormal physiological values recorded in the preceding period, as do patients requiring transfer to the ICU. [3, 33, 37]

RRS rely on systems that track an agreed set of vital signs (oxygen saturation, pulse, blood pressure, temperature and level of consciousness as well as other indicators such as urine output and pain [36]) and recommend a call if a threshold value has been triggered. Physiological monitoring algorithms are therefore often described as ‘track and trigger systems’. Many different track and trigger systems have been developed, [38, 39] broadly categorised as single- or multiparameter systems, aggregate weighted scoring systems (such as EWSs) or combinations (Box 2.2). [14] The patient’s measured vital signs are compared with a set of reference values, with measurements above or below designated points used as triggers for escalation. For EWSs, points are awarded for defined levels of physiological abnormalities. Improvement or further deterioration can then be tracked by changes in the EWS recorded over time so that an EWS used in this way can be described as a ‘track and trigger system’.

Box 2.2

Classification of track and trigger warning systems

Single-parameter systems

- Tracking: periodic observation of selected basic signs
- Trigger: one or more extreme observational values

Multiple-parameter systems

- Tracking: periodic observation of selected basic vital signs
- Trigger: two or more extreme observational values

Aggregate weighted scoring systems

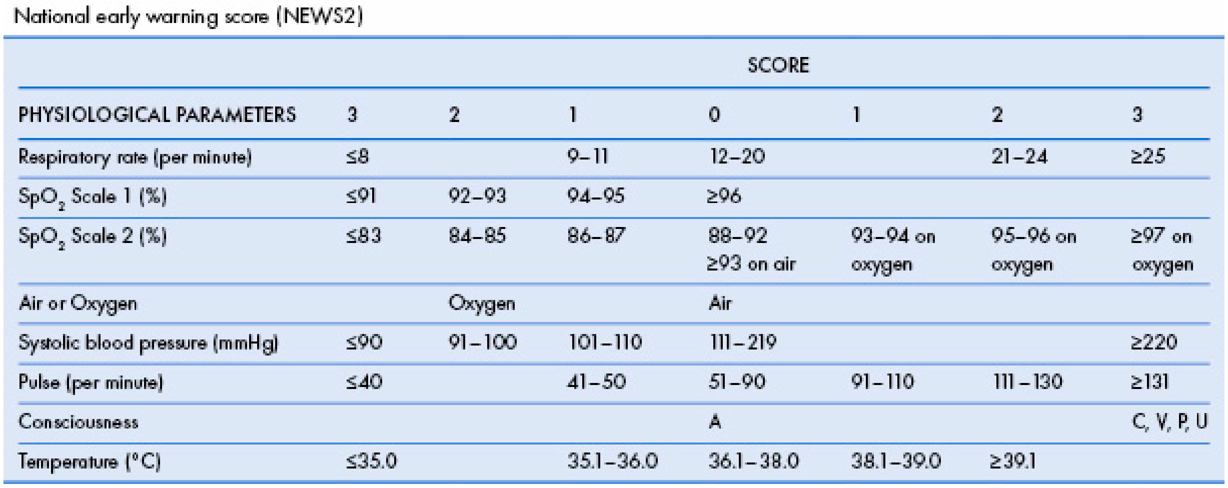
- Tracking: periodic observation of selected basic vital signs and the assignment of weighted scores to physiological values with the calculation of a total score
- Trigger: achieving a previously agreed trigger threshold with the total score

Combination systems

- Elements of single- or multiple-parameter systems in combination with aggregate weighted scoring

The high number of published systems has led to calls for standardisation to improve training and reliability of response, with the United Kingdom's National Early Warning Score (NEWS) published in 2012 [40] and revised in 2017 (Table 2.1). [41] A different approach has been taken by Australian METs, where the escalation criteria are usually based on single, markedly deranged physiological values, supplemented by ward staff concern as a trigger (Table 2.2). [25]

Table 2.1



National early warning score (NEWS2)

	SCORE						
PHYSIOLOGICAL PARAMETERS	3	2	1	0	1	2	3
Respiratory rate (per minute)	≤8		9–11	12–20		21–24	≥25
SpO_2 Scale 1 (%)	≤91	92–93	94–95	≥96			
SpO_2 Scale 2 (%)	≤83	84–85	86–87	88–92 ≥93 on air	93–94 on oxygen	95–96 on oxygen	≥97 on oxygen

Table 2.2

Medical emergency team call-out criteria as used in the MERIT study

Airway	Threatened
Breathing	Respiratory rate <5 or >36 per min
	Respiratory arrest
Circulation	Pulse rate <40 or >140 per min
	Systolic blood pressure <90 mm Hg
Neurology	Sudden fall in level of consciousness (fall in GCS of >2 points)
	Repeated or extended seizures
Other	Any patient you are seriously worried about

GCS , Glasgow Coma Scale.

From Hillman K, Chen J, Cretikos M, et al. Introduction of the medical emergency team (MET) system: a cluster-randomised controlled trial. *Lancet* (London, England). 2005;365(9477):2091–2097.

Alternative systems to risk-stratify patients based on laboratory parameters alone, [42] laboratory parameters in conjunction with vital sign observations, [43] or indicators of acute physiology, chronic illness and functional status [44] have all been validated. Another method is to promote the reporting of clinical indicators, such as noisy breathing or changes in colour; for example the Dutch-Early-Nurse-Worry-Indicator-Score, [45] a prospective evaluation of a Nurse Intuition Patient Deterioration Scale with 10 items showed excellent discrimination to predict an event within 24 hours of measurement. [46]

The efferent limb: setting up the response team

Patients with potential or actual critical illnesses are found in every area of the hospital, so systems to identify and treat those patients need to be planned at an organisational level. Involvement of managerial and clinical staff is essential, especially from the wards. It is particularly important that there is agreement and clarity about how the outreach team or equivalent interacts with the parent or primary medical team.

The composition and skills of the team should be designed to meet the particular needs identified by the organisation. At a minimum, the team should be capable of assessment, diagnosis, initiation of resuscitation and rapid triage of critically ill patients to higher levels of care. Such clinical competencies as airway management, venepuncture and cannulation are essential, as are skills in education, audit and research. Leadership, coordination and communication skills are also crucial. There is currently no conclusive evidence to recommend a nurse- or doctor-led team, but at the time of writing this chapter, investigations are ongoing.

The UK Department of Health has detailed the competencies required for the care of at-risk and deteriorating patients, specifying what should be expected of junior, middle-grade and senior staff.[47]

A pragmatic, staged implementation could include:

1. Establishing an education programme in the care of the deteriorating patient for ward staff so that they can recognise signs of deterioration and know how to obtain timely help.
2. Introducing a physiological track and trigger warning system with defined referral and response protocols.
3. Developing clinical bedside support – incrementally if necessary – increasing gradually the number of clinical areas covered by the team, and the hours of work. This might include follow-up of patients discharged from critical care and responding to patients identified through the track and trigger system or by other means.[14]

The Australian Commission on Safety and Quality provides a useful guide to setting up and developing an RRS, [48] and the UK's National Outreach Forum has published a competency framework for members of the response team. [49] A checklist of key points for consideration when planning a rapid response system is set out in Box 2.3 .

Box 2.3

Checklist for planning a rapid response system

- Appoint senior clinical and managerial leads to develop the service.
- Institute organisational needs analysis, audit and evaluation, asking:
  – Which patients are at risk of deterioration and where are they located?
  – Where do cardiac arrests and unexpected deaths occur?
  – What are the sources of unplanned admissions to the ICU?
  – What is the pattern of adverse events where harm can be attributed to processes of care?
  – What are the other relevant clinical governance/risk management issues or morbidity and mortality data?
- Undertake a point prevalence studies to give a snapshot view of the location of patients at risk.
- Review unplanned admissions to the ICU to identify systems failings, including quality of patient management and the appropriateness and timeliness of escalation.
- Analyse staff training needs.
- Consider: existing skills of ward staff, proposed hours of service, likely demand.
- Liaise with existing complementary services, such as tracheostomy specialists, respiratory specialists, renal specialists, pain teams and night teams etc.
- Identify training facilities.
- Plan service location and equipment needs including information technology.

- Negotiate funding.

The Administrative Limb: Systems to Measure Process, Outcomes and Impact

It is essential that robust data are collected and used for audit and evaluation – and for feedback to operational managers and clinical staff. Successes should be highlighted and areas for improvement identified.

Process metrics may include the number of referrals and patient follow-ups, date and time of each episode, patient details (e.g. age, gender, date of hospital admission, location, emergency/elective admission, medical/surgical status and resuscitation status), the call-out trigger event (e.g. EWS and cardiac arrest call), significant problems identified, clinical interventions performed and patient outcomes.

The use of RRSs is based on the premise that early detection and treatment of critical illnesses should improve patient outcomes, such as rates of cardiac arrests, need for organ support or mortality. Changes in outcomes might be driven by changes in process metrics such as the number of staff trained, the completeness of bedside observations, the timeliness of escalation, the speed of response and the time from patient trigger to transfer to an ICU – or the initiation of critical care treatment on the ward (i.e. the ‘Score-to-Door time’ [50]).

Table 2.3 shows one method that can be used to evaluate the outcomes of RRS interventions 24 hours after the initial event, with outcomes classified as either positive or negative. The proportion of positive interventions provides a measure of the quality of the service. This approach has now been used in two multinational multi-centre studies of RRS, enabling benchmarking and learning from others to occur. The first report, from 51 hospitals in five countries, found that, on average, urgent transfer to the ICU occurred in 24% of patient referrals, while new treatment limitations were instigated in 28% of patients not transferring to the ICU. Mortality just 24 hours after referral was 10.1%. [51]

Table 2.3

DNACPR, Do not attempt cardiopulmonary resuscitation.

From Morris A, Owen HM, Jones K, et al. Objective patient-related outcomes of rapid-response systems—a pilot study to demonstrate feasibility in two hospitals. *Crit Care Resusc* . 2013;15(1):33–39.

An international consensus conference in 2018 agreed on 10 metrics to describe the quality of an RRS based on the Institute for Healthcare Improvement's quadruple aim. [52] Recommended as essential were the number of cardiac arrests and the proportion of those that occurred after documented abnormalities in the preceding 24 hours. Also recommended were monitoring of the timeliness of response to abnormal vital signs and timeliness of intensive care type of treatments. Direct access by patients and their families to an RRT was recommended too. There were difficulties in identifying suitable economic metrics beyond the length of stay in the ICU or hospital.

Emerging Trends

Mature RRSs experience challenges from rising demand and the charge that they deskill ward staff. One possible solution is a two-tier response system where the patient's parent team is equipped to provide a defined initial response in the first instance, [53] with the MET only activated if a more severe illness is identified. [54]

It is clear that many errors causing 'failure to rescue' are due to human factors and flaws in the design of hospital systems, [55], [56] as illustrated by the MERIT study finding that patients needing escalation to the ICU with signs that should have been reported to the MET, only 30% were actually referred. [25] Hierarchical thinking, inflexible mental modelling, unreliable performance and uncoordinated, inefficient organisation are all factors. [55], [56] Even relatively simple matters, such as the documentation of vital sign recording, have a role: attention to the design of charts may promote more reliable detection of deterioration.[57]

Automation has great potential to improve the reliability of some important processes. Technologies that provide continuous or semi-continuous monitoring of vital signs, automatically calculate the EWS and communicate critical values are available, with the first clinical trials suggesting better outcomes but with limited insights into the conditions under which they work,[58] while checklist-based interventions might help standardise the response to deterioration.[59],[60] The development of increasingly sophisticated expert systems will enable the analysis of patterns of physiological data that can produce specific alerts as well as prompts and advice about individual patients.

More sophisticated monitoring algorithms that go beyond vital signs and use machine learning have been under development for over a decade, but only recently has testing focused on actual clinical results. Escobar et al.[61] implemented a novel algorithm in 19 hospitals in a stepwise fashion and were able to demonstrate improvements in mortality in at-risk patients in the intervention group. Winslow et al.[62] undertook a multi-centre study of a different algorithm, again demonstrating improved mortality in the at-risk group and earlier reassessment of vital signs.

There is a greater emphasis on the involvement of patients or their relatives, allowing those who know a patient well to escalate care. This method was first used in paediatric settings but is increasingly being explored for adults, with examples from the United States (Lewis Blackman Patient Safety Act),[63] Australia (‘Ryan’s Rule’)[64] and the United Kingdom (‘Call 4 Concern’).[65] Interest is driven by two developments: Post COVID-19, more patients have access to wearable monitoring equipment that would allow them to assess the degree of physiological instability themselves; and a number of recent high-profile failures in patient safety, together with a greater emphasis on shared decision making have led to new initiatives to facilitate patient and family escalation mechanisms.[66]

Conclusion

The RRS represents one method of reducing failure to rescue deteriorating patients in hospital wards. Structured systems for classifying risk and physiological abnormalities and protocols for response can help reduce adverse events, including cardiac arrests, preventable intensive care admissions and possibly the costs of care for acutely ill patients.

Critical care nursing

John Robert Welch

Nature and Function of Critical Care Nursing

Nurses are the round-the-clock, safety-critical, constant factor for critically ill patients and their families, ensuring continuity and acting as the glue that holds the intensive care unit together. Nurses fine-tune, coordinate and communicate all the aspects of care and treatment needed for patients ‘*at high risk for actual or potential life-threatening health problems*’,[1] including:

- continuous, close monitoring of patients and the attached equipment,
- dynamic analysis and synthesis of complex data,
- anticipation of complications,
- complex decision making, execution and evaluation of interventions – to minimise adverse effects,
- enhancement of speed and quality of recovery,
- emotional support of the patient and family, including support through the end of life.

There are increasing shortages of critical care nurses in many countries, a worrying trend, while there are also increasing demands for critical care services, intensified by the experience and aftermath of the COVID-19 pandemic. A group of world-leading clinicians listed ten approaches to help attract and retain nurses in this climate, beginning with recognising and valuing the unique contribution of nursing in critical care.[2] Insufficient nurse staffing leads to poorer outcomes [3] and has more effect on high-risk patients than levels of medical staffing. [4] Supporting nurses’ personal and professional development, their active involvement in collaborative, multidisciplinary teamwork, their wellbeing and the re-humanising of patient care are essential for the future of the service. [2]

Nursing in critical care is influenced by the essential nature of nursing as well as the specifics of the specialty. Key concepts for all nurses include an appreciation of holism – the whole range of influences on all aspects of life – and the pursuit of health rather than treating illness. [5] Nevertheless, critical care nurses must be technically competent. Even routine tasks such as titration of inotropes and vasopressors and ensuring a constant flow of these medications when syringe drivers are changed are significant skills. [6] This means it is possible that human and humanising components of care can be neglected; one patient described his experience as ‘ *rooted in the minute analysis of charts and the balancing of chemicals, not so much in the warmth of human contact* ’. [7] Critical care patients report experiencing breathlessness, voicelessness and thirst and feelings of helplessness, anxiety, desperation, desertion and powerlessness. [8-10] Expert nurses connect with their patients physically and psychologically, [11] but crucial aspects of person-centred care are lost when the nursing resource is depleted. [12] This is an important issue; for example, rigorous oral hygiene care both improves patient experience and reduces the risk of developing ventilator-associated pneumonia. [13]

Intensive care unit (ICU) patients are less sedated and thus more aware than previously, ‘ *conscious but feeling doped* ’. [8] They can rarely control what happens to them during critical illness, especially in the acute phase, but usually want to reassert their autonomy as they recover, for example, when weaning from ventilation or moving to a lower level of care. Nurses can enable patients to exercise autonomy at these points while still ensuring safe progression. Moreover, essential personal care is invariably undertaken or supervised by nurses, and although important functions, such as chest physiotherapy, mobilisation and administration of nutrition may be prescribed by other specialists, they will still be integrated and usually delivered by nurses.

A Systematic Approach to Care

Nursing critically ill patients is complex. A clinical review should be structured to clarify and prioritise patient needs so that all possible problems are addressed. In acute situations, assessment in turn of the fundamental A–B–C–D–E aspects of care is a useful method:

A irway: establishing and maintaining airway patency (using airway adjuncts or advanced airways as necessary; with humidification, removal of pulmonary secretions, etc.).
B reathing: ensuring the adequacy of oxygenation and ventilation.
C irculation: assessing blood volume and pressures; perfusion of brain, heart, lungs, kidneys, gut and other organs; control of bleeding etc.
D isability: checking consciousness and the factors that influence it, systemic and localised neurology; assessing the need for analgesia, sedation and neuromuscular blockade.
E xposure: hands-on, head-to-toe, front-and-back examination and review of everything else; with consideration of skin and mucus membrane integrity, wounds and drains.

Treatment strategies can be prioritised using this schema, which has the additional benefit that it will be familiar to those trained in advanced life support and similar methods. Further detail may be gained from a review of:

F luid and electrolyte balance, biochemistry.
G astrointestinal function: nutritional needs; elimination.
H istory and holistic overview of the patient as a person – and their sociocultural background.
I nfection and infection control; microbiology – and personal hygiene.
L ines, catheters/invasive devices; utility and risks.
M edications.
N ursing and multidisciplinary teamwork; ensuring that the staff resource is sufficient for the patient’s severity of illness and the

physical demands of care.

O ral/dental care.

P sychology (cognition, consideration of delirium, communication and mood) – and the **p** lan of care and prognosis in the short, medium and long term. [14]

R elatives, loved ones and carers.

More sophisticated models can be used to frame a wider impression of the patient or to reflect a particular philosophy or approach to care. There is a benefit in developing a shared vision within the department, and in articulating how agreed values will be demonstrated in practice. [15] These might include emphasising the primary importance of patient safety and experience, ensuring that the kindness an individual would want for their loved ones is always offered, as well as effective teamwork, and systems in place to achieve continuous improvement. Whichever method is used, there must be explicit definitions of the patient's problems, a clear statement of measurable therapeutic goals and clarity of who in the team will deliver which aspects of care and treatment.

Nursing and Patient Safety

Many patients suffer iatrogenic harm in the ICU, [16] but vigilant nurses can prevent such incidents by intercepting and mitigating errors that may be made by others. [17] Ways of deploying critical care nurses differ around the world and no particular approach has been shown to be definitively superior [18] ; more research is needed on this matter. Nonetheless, nursing surveillance is key to patient safety. [19] Insufficient staffing is linked to increased numbers of adverse events, morbidity and mortality. [4, 20] At a minimum, 5.6 whole-time equivalent nurses should be employed for each patient requiring 1:1 care 24 hours a day. Familiarity with other nursing team members is important too [21] ; ICUs with high proportions of non-permanent staff are more likely to have patient safety issues.

Evolving roles in critical care nursing

Nurses constitute the largest part of the workforce and represent a significant cost, even more so when staff retention is poor. Maintaining sufficient numbers of staff with the experience, skills – and motivation – to meet the increasing needs of critically ill patients is a major challenge. [2] Changes in training arrangements (e.g. the withdrawal of bursaries for new nursing students in the NHS) and the demographics of nurses in general also contribute to fewer applications for ICU posts. The array of tasks undertaken by critical care nurses in different institutions and different countries varies, although invasive procedures and drug prescriptions are still mostly performed by doctors. [22] However, suitably trained nurses working in advanced critical care practitioner (ACCP) or similar roles increasingly undertake these functions too, not yet on a large scale, but likely more and more in years to come.

The benefits of developing new skills must be balanced with the maintenance of essential holistic care while critical care nurses' scope of practice continues to grow in most areas, partly due to progress in technology, and with changes in the working of other professionals. Critical care nurses routinely have a large role in decision making regarding adjustment, titration and troubleshooting of key treatments such as ventilation, fluid management, inotrope/vasopressor administration and renal replacement therapy. The use of less invasive techniques such as transoesophageal Doppler ultrasonography for cardiac output estimation makes it easier to institute sophisticated monitoring and modify treatments accordingly. There is evidence that nurses can achieve good outcomes in these areas (e.g. reducing the time to wean respiratory support [23]), especially when aided by appropriate protocols, guidelines and care pathways. [24]

Workforce challenges and increasing demand for critical care services have driven the development of new ways of working to deliver both fundamental and more sophisticated aspects of care. New nursing roles include some that substitute for medical roles as well as those that retain a nursing focus and aim to fill gaps in healthcare with nursing rather than medical practice. For example senior 'nurse consultant' posts have been created in all areas of United Kingdom healthcare, but the largest proportion is in critical care, particularly in outreach roles. [25] These individuals are experts in clinical practice but also provide professional leadership and consultancy, clinical and academic education and training, together with service development, research and evaluation.

Leadership, education and research are included in ‘advanced critical care practitioner’ job descriptions, but their primary focus is very much advanced clinical practice and autonomous working in defined situations previously considered the domain of doctors. There is now a critical mass of NHS ICUs employing or training ACCPs. [26] Trainees come from a variety of healthcare backgrounds but are usually experienced critical care nurses undertaking postgraduate/master’s-level training, typically over two to three years. These programmes include the acquisition of advanced clinical assessment skills, the performance of diagnostic tests, diagnosis and clinical reasoning, initiation and management of treatment plans, invasive procedures (e.g. central line placement and – increasingly – advanced airway techniques) as well as non-medical prescribing. [27] Analysis of ACCPs in practice indicates that their enactment of potentially high-risk activities such as advanced airway manoeuvres and transfer of ventilated patients is of a quality comparable to that of their medical colleagues. [26]

Other staff such as nursing/healthcare assistants are increasingly and successfully employed to deliver what has previously been seen as core nursing care so as to support trained nurses and free them to concentrate on more advanced practices. [28] Reductions in healthcare funding and shortages of trained staff are likely to make such developments more common, but it is imperative that this is a managed process to ensure the best outcomes for patients. There need to be proper arrangements for training, support and systems of work.

Critical Care Nursing Beyond the ICU: Rapid Response Teams and Critical Care Outreach

Around the world, general ward staff are required to manage an increasing throughput of patients who are, on average, older than before, with more chronic disease and more acute and critical illness. Studies of critically ill ward patients show that many experience substandard care and adverse events before transfer to the ICU. [29] Various factors are implicated, including knowledge deficits and failures to appreciate clinical urgency or to seek advice, often compounded by poor organisation. It is nurses who record or supervise the recording of vital signs, but there is often inadequate understanding of the significance of these values or ineffective communication with senior staff and difficulties ensuring that appropriate treatments are prescribed and administered. There is an ongoing debate about whether dedicated rapid response or outreach teams supporting ward staff in such situations should be nurse- or physician-led; there is no definitive evidence either way. Nurse-led critical care outreach teams have been effectively supporting ward staff caring for at-risk and deteriorating patients – as well as facilitating transfer to ICU when required – for over 20 years.[30], [31] They can also support the care of patients on wards after discharge from ICU,[32] and after discharge from the hospital. Potential problems with these approaches include loss of specialist critical care staff from the ICU, and being sure that outreach teams have the necessary skills to manage high-risk patients in less well-equipped areas, particularly if there are limitations placed on nurses prescribing and administering treatments.

Nursing in the Multidisciplinary Team

High-quality critical care requires genuine multidisciplinary teamwork, with:

- clarity of individual roles and understanding of the roles of others,
- team members that share knowledge, skills, best practices, and learning,
- systems that enable shared decision making, goal setting, clinical governance, individual and team accountability, risk analysis and management,
- mechanisms to resolve differences of opinion or conflict.[33]

Teams perform most effectively when individuals believe that they are working towards meaningful common goals. The principles of shared governance can be usefully applied in this area, whereby staff collectively review and learn from their own practices. This must be in the context of:

- the strategic agendas of the unit and the hospital,
- the development of the service,
- an appreciation of the realities of day-to-day working of different team members,
- financial issues, budgets and budgetary restraints.

ICUs with less well-developed team performance are likely to have fewer effective processes and poorer outcomes. [34] The evidence is that ensuring and improving the quality of teamwork is more important still when team members have diverse backgrounds or different understandings of the ways of working when teams are relatively large in size, and when the work has significant non-routine aspects (e.g. non-elective or emergency cases) [34] ; that is exactly the characteristics of many modern ICUs.

Features of team leadership, coordination, communication and decision making can be assessed against defined criteria, as can indicators relating to patients and staff, [35] for example:

- compliance with guidelines,
- review and learning from adverse events/critical incidents,
- patient length of stay,
- mortality,
- staff satisfaction and experience,
- staff retention.

Identified deficiencies in teamwork can then be addressed, although some investment may be needed. One study focused on nurses as the main drivers of improvement in the ICU. Units were engaged in a structured improvement programme involving analysis of the prevailing culture in the department, followed by tailored training in teamwork, ways of achieving safer practices and performance measurement. [36] ICUs that completed the programme had significantly better outcomes than those that did not, even though both groups were required to use the same clinical protocols. [36]

Quality of Care and Quality Improvement

Robust measurement and analysis of structures, processes and outcomes are the foundation of quality care. Similar quality measures have been described for healthcare systems around the world,[37], [38] although it is noteworthy that not all set out structural components such as the 'presence of an oxygen plant to deliver medical grade oxygen'[38] that are taken for granted in high-income countries. Typical indicators might include pressure ulcer prevalence, nosocomial infection rates, or drug administration errors. Nurses must take responsibility for the care they deliver, although it should be appreciated that nursing practices cannot be considered entirely separately from other variables that influence patient outcomes: quality care depends on a collective interdisciplinary commitment to continuous improvement,[39] and continuous 'measurement for improvement'. Understanding the patient, patient family and staff experience is essential too[40]; patient outcomes are intrinsically linked to patient and staff experience. One approach is to assess the evidence of care of a representative sample of patients every month, or, better still, weekly. Some descriptors of critical care nursing quality are shown in Box 3.1 . Analysis of the data will reveal which areas of care need attention, where variations in care exist, and trends over time. It is desirable to compare data and to share learning with other ICUs where possible.

Box 3.1

Exemplar critical care nursing quality indicators

Randomly select patients and check:

Airway

- Airway management and turning/repositioning plan.
- Emergency equipment by the bedside (for those with altered airways).

Pain

- Pain – and nausea – score recorded hourly.
- Plan for managing postoperative pain.
- Is the patient in pain at the time of review?

Sedation

- Richmond Agitation and Sedation Scale (RASS) assessed hourly.
- If appropriate, target RASS in the Care Plan.
- Confusion Assessment Method for ICU (CAM-ICU) assessed daily.

Maintaining skin integrity

- SSKIN (**S**kin Assessment, **S**urface, **K**eep moving, **I**ncontinence, **N**utrition assessment) completed and documented within an hour of admission.
- Risk assessment completed every shift.
- SSKIN bundle completed every shift.
- Patient on the correct mattress.
- Patient on the correct turn frequency.
- The nurse can describe an appropriate pressure ulcer prevention plan for the patient.
- Strategies in place to prevent incontinence-associated dermatitis/moisture damage.
- Strategies in place to prevent damage from medical devices.
- Patient/carer understands the pressure ulcer prevention plan.
- Manual handling assessment completed in last 24 hours.

Monitoring

- Safe alarm limits set.
- Fluid balance target identified.
- Fluid challenge used as per protocol.
- Fluid balance target achieved.

- Invasive lines: documented evidence of insertion and removal.
- Lines visibly clean and dressings intact.
- Infusion lines are clearly labelled and in date.

Assessment and documentation

- Time of admission/transfer clearly documented.
- Multidisciplinary Team care plan with problems identified and clear treatment goals.
- Accurate A–E nursing review and evaluation on each shift.
- Documented evening review.
- Documented night shift review.
- Complete Multidisciplinary Team discharge summary (when appropriate).
- Up-to-date patient information board.

Critical care nursing leadership and management

Engaged, credible and visible nurse leadership is essential to the performance of the ICU, to safety and to patient and staff experience. One review found that ‘considerate, exemplary practices, and transformational and trusted leadership styles guarantee a better quality of care’. [41] A main priority is the challenge of attracting and retaining a flexible and progressive nursing team that works effectively with other healthcare professionals to meet patient needs – within a limited budget.

Staffing the Critical Care Unit

Optimal staffing levels are associated with fewer complications, lower mortality and costs of care, as well as better family and staff experience and satisfaction.[3] The starting point for the calculation of staffing requirements is the detailing of patient needs – and of the knowledge and skills that will be required to meet those needs – with an appreciation that there will be variations over time, some of which are unpredictable (Box 3.2). Equity of services and opportunities to compare the results of changes in staffing are aided by having agreed standards, for example, as described in UK 'Guidelines for the Provision of Intensive Care'[42] (Box 3.2) and Australian College of Critical Care Nurses 'Standards for Intensive Care Nursing'.[43]

Box 3.2

Standards for nurse staffing in critical care

- Level 3 patients (receiving advanced respiratory support alone or basic respiratory support as well as support of at least two other organ systems) must have a registered nurse/patient ratio of a minimum 1 : 1 to deliver direct care.
- Level 2 patients (requiring more detailed observation or intervention including support for a single failing organ system, or postoperative care, or 'stepping down' from a higher level of care) must have a registered nurse/patient ratio of a minimum of 1 : 2 to deliver direct care.
- Each designated critical care unit must have an identified lead nurse with overall responsibility for the nursing elements of the service.
- There must be a senior registered nurse working as a supernumerary clinical coordinator on duty 24/7. (Units with <6 beds may consider having a supernumerary clinical coordinator to cover peak activity periods, for example, early shifts.)
- Units with >10 beds must have additional supernumerary registered nursing staff over and above the clinical coordinator to enable the delivery of safe care (i.e. 11–20 beds +1 and 21–30 beds +2). The

number of additional staff per shift will be incremental depending on the size and layout of the unit (e.g. in the case of multiple single rooms) and during events such as infection outbreaks.

- Each unit must have a dedicated clinical nurse educator responsible for coordinating education, training and continuing professional development for nursing staff and pre-registration students. This should equate to a minimum of 1.0 whole-time equivalent per 75 nursing staff.
- All nursing staff appointed to critical care will be allocated a period of supernumerary practice to enable the achievement of basic specialist competence.
- A minimum of 50% of registered nursing staff must be in possession of a post-registration academic programme in Critical Care Nursing.
- Units must not utilise >20% of a registered nurse from the bank/agency on any one shift when they are NOT their own staff.
- Where direct care is augmented using unregistered/support staff, appropriate training and competence assessment are required.
- In addition to leadership competencies the lead nurse/matron/senior nurse must meet, as a minimum, the same specialist critical care nurse educational standards as the staff caring for Level 3 patients.

From Faculty of Intensive Care Medicine & Intensive Care Society. *Guidelines for the provision of intensive care services* . V. 2.1. London: Faculty of Intensive Care Medicine & Intensive Care Society; 2022.

The patient need has many components, including:

- the severity and complexity of acute illness and chronic disease,
- other physical characteristics (e.g. mobility, body weight, skin integrity and continence),
- consciousness and cognition,
- mood and emotionality (e.g. anxiety, depression and motivation to engage in rehabilitation),

- the frequency and complexity of observation/monitoring and interventions,
- the needs of relatives.

The staff resource includes members of the clinical team and the whole range of ancillary staff and support services. Collectively, these personnel must be adequate to meet patient needs. This requires evaluation of:

- nursing numbers and skill mix,
- multidisciplinary team skill mix, with consideration of variations in the availability of team members out-of-hours (e.g. doctors, respiratory/physiotherapists and equipment technicians).

The context of care is also significant; that is:

- the physical environment (e.g. the ease with which patients can be observed, whether cohort in groups or in separate rooms),
- workload variations – peaks, troughs and overall activity in the department (e.g. admissions, discharges, transport to other areas [e.g. for imaging] and transfers).

The nurse leader/manager is also responsible for:

- coordinated operational management of the area,
- quality of nursing care,
- management of nursing pay and non-pay budgets,
- personnel management,
- dealing with complaints and investigating adverse incidents.

There are always dynamic political, social and economic forces affecting the organisational objectives and resources of the hospital and the ICU. Critical care is a crucial but often small part of the whole patient journey. The nurse leader/manager needs to understand these factors and connections and how they influence the delivery of patient care and the maintenance of a healthy environment for individual and team development. The key issues must be clarified and communicated to the whole team in the form of an agreed strategy and a clear, regularly updated operational plan for the department. This requires there to be a working system that addresses and integrates the views and needs of all users of the service, including patients and their families [40] ; with proper consideration of how the service can be made equitable, feel inclusive and be considerate of the diversity of patients and staff. Such a system should enable a shared understanding of exactly what needs to be done in practice and where each team member fits into the work plan. Externally, the manager represents the service and ensures that other disciplines and the bigger organisation are informed about critical care issues.

Management of Staff Stress and Motivation

The ICU can be extremely stressful, demanding considerable cognitive, emotional and psychomotor effort from staff. Supervisory and feedback arrangements should be in place to help manage these demands and to identify staff members who are having difficulties at work. Studies of human resource practices demonstrate an association between quantity and quality of staff appraisal and hospital mortality, and that organisations that emphasise training and teamwork have better outcomes. [44] Similarly, staff survey data show that staff wellbeing correlates with hospital mortality. [45] Regular individual performance reviews and formulation of personal development plans provide positive assurance and encouragement for staff and can identify specific individual requirements such as pastoral or psychological care or educational needs.

The usual stresses of critical care nursing described above were exponentially intensified during and since the COVID-19 pandemic. A survey of American critical care nurses from October 2020 to January 2021 – sometime before patient numbers returned to normal levels – found that they suffered much more anxiety and depression than the general population (31% vs. 19% and 44.6% vs. 8%, respectively) and were at greater risk for post-traumatic stress disorder than combat veterans or victims of trauma. [46] 42.9% of Belgian critical care nurses surveyed a year later expressed an intention to leave their jobs, although, importantly, those from hospitals in the top quartile of work environments were at significantly less risk of burnout and intention to leave than those from hospitals in the lowest quartile of work environments.[47]

Providing staff at all levels with opportunities to influence and perhaps modify the working environment can decrease stress and increase motivation – and improve outcomes.[45] Flexibility to work in different ways at different times while still meeting the overall demands of the department is important. It is the manager's job to balance and meet the needs of staff, patients and the organisation. One method is to give staff a choice regarding rostering, partly to help with work–life balance, but also so that the nurse can opt to work with particular patients for a time to practice certain skills – and to additionally provide continuity of care. This can have real benefits for staff and patients.

Nurse Training and Education

There are many well-established educational programmes for critical care nurses, although the content and requirements vary.[48] There is a role for the study of relevant nursing philosophy, theory and research methods, but the fundamental requirement is for learning that focuses on clinical practice and practical problem solving (Box 3.3).

Box 3.3

Key competencies for critical care nurses

Respiratory system : Anatomy & Physiology, Assessment, Monitoring & Observation, Non-Invasive Ventilation, Endotracheal Intubation, Invasive Ventilation, Chest Physiotherapy, Tracheostomy Care, Chest Drain Management, Associated Pharmacology.

Cardiovascular system : Anatomy & Physiology, Assessment, Monitoring & Observation, Arterial Access, Central Venous Access, Fluid Management, Sepsis Management, Shock Management, Cardiac Rhythms, Associated Pharmacology.

Renal system : Anatomy & Physiology, Assessment, Monitoring & Observation, Renal Replacement Therapy, Associated Pharmacology.

Gastrointestinal (including liver and biliary) system : Anatomy & Physiology, Nutrition in Critical Illness, Assessment and Management, Associated Pharmacology.

Neurological system : Anatomy & Physiology, Assessment, Monitoring & Observation, Sedation & Delirium Assessment and Management, Pain Control.

Integumentary system : Anatomy & Physiology, Skin Integrity, Joint Positioning & Range of Movement, Venous Thromboembolism Assessment.

Other essential areas

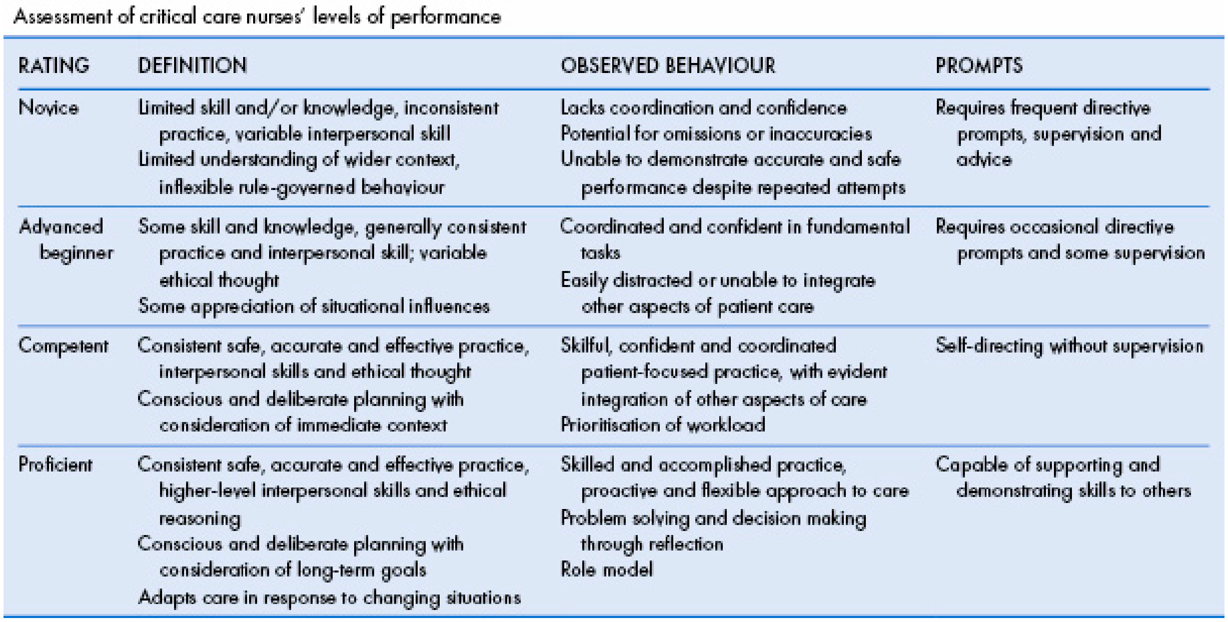
- Promoting a Positive Patient Experience (Psychosocial Wellbeing, Visiting in Critical Care)
- Medicines Administration
- Admission & Discharge
- End-of-Life Care
- Intra- & Interhospital Transfer
- Rehabilitation
- Communication & Teamwork
- Infection Prevention & Control
- Evidenced-Based Practice
- Professionalism
- Defensible Documentation
- (Assessment of) Mental Capacity
- Leadership

From Bruyneel A, Bouckaert N, Maertens de Noordhout C, et al. Association of burnout and intention-to-leave the profession with work environment: a nationwide cross-sectional study among Belgian intensive care nurses after two years of pandemic. *Int J Nurs Stud* . 2023;137:104385.

A competency framework can be used to structure descriptions of the skills, knowledge and attitudes needed to achieve specific outcomes. There needs to be consideration of how individual actions are integrated into holistic care and of the role of independent clinical judgement. Developing nurses' critical thinking and decision-making skills is also important. Appraisal of learners' performances requires assessors to observe and question the nurse in practice, although this places significant demands on hard-pressed clinical areas. High-fidelity simulation is increasingly used to test and consolidate performance away from the practice setting.

Descriptors of different levels of performance have also been developed; based, for example, on Benner's novice-to-expert hierarchy (Table 3.1). UK critical care nursing organisations have set out three initial stages of development. This gives novice critical care nurses 12–18 months to acquire core competencies under supervision (Step 1). They then work through an approved academic programme to enable practice without direct supervision (Step 2 and Step 3), [49] typically over another 18 months. Progression all the way from novice status to achieving proficiency in critical care nursing takes 6 years or more; that is to have the capability of being in charge of shifts in the ICU and leading a team.

Table 3.1



Assessment of critical care nurses' levels of performance

RATING	DEFINITION	OBSERVED BEHAVIOUR	PROMPTS
Novice	Limited skill and/or knowledge, inconsistent practice, variable interpersonal skill Limited understanding of wider context, inflexible rule-governed behaviour	Lacks coordination and confidence Potential for omissions or inaccuracies Unable to demonstrate accurate and safe performance despite repeated attempts	Requires frequent directive prompts, supervision and advice
Advanced beginner	Some skill and knowledge, generally consistent practice and interpersonal skill; variable ethical thought Some appreciation of situational influences	Coordinated and confident in fundamental tasks Easily distracted or unable to integrate other aspects of patient care	Requires occasional directive prompts and some supervision
Competent	Consistent safe, accurate and effective practice, interpersonal skills and ethical thought Conscious and deliberate planning with consideration of immediate context	Skilful, confident and coordinated patient-focused practice, with evident integration of other aspects of care Prioritisation of workload	Self-directing without supervision
Proficient	Consistent safe, accurate and effective practice, higher-level interpersonal skills and ethical reasoning Conscious and deliberate planning with consideration of long-term goals Adapts care in response to changing situations	Skilled and accomplished practice, proactive and flexible approach to care Problem solving and decision making through reflection Role model	Capable of supporting and demonstrating skills to others

Critical care nursing research

Research is most valued when it is relevant to practice. The researcher is more likely to gain support for the investigation of high-risk and high-cost procedures and processes, but many everyday treatments and activities warrant examination too, particularly when there are significant variations in practice. The researcher should aim to determine how the topic of interest might be described in a measurable way, and to formulate the investigation as a question, with consideration of how answers can be obtained.

Relatively small numbers of patients are treated in the ICU at considerable cost, although many of the methods used do not have a completely robust evidence base. Patient outcomes are influenced by different organisational approaches, staff characteristics, varied working practices and differences between patients themselves. Therefore a range of both quantitative and qualitative investigative procedures may be needed to gain a full understanding of critical issues, including human factors, consideration of human behaviour in practice, and the challenges of implementation at scale. The approach chosen depends on the nature of the research question, the objectives of the researcher and the resources available. For example:

- Comparing different treatments generally requires quantitative measurements of particular endpoints (e.g. the dose of a drug needed to achieve a target physiological variable).
- Understanding how an individual thinks or feels usually involves analysis of qualitative material (e.g. data from interviews with patients and families).

It is noteworthy that few large trials of medical treatments in the ICU have shown sustained, significant benefits in recent years. An ‘ICU Priority Setting Partnership’ identified three critical questions for ICU patients, carers and clinicians [50] :

1. How might patients who would benefit from critical care best be identified and admitted at the optimal time?
2. How can patients and their families best be helped through often lengthy phases of recovery and rehabilitation from critical illness?
3. How best can delirium and agitation be prevented or managed when they occur?

Answering these questions is ongoing work, but nurses have already extensively researched the second and third questions in particular; the qualitative methods they often use are very appropriate for further developments in these areas.

There is great potential for nurses to be leaders in such matters, and also to address important policy issues, including those recently identified by an international survey of critical care nursing organisations, that is, how nurses – and their patients – can best be served by improving:

- working conditions,
- teamworking,

- staffing levels,
- practice guidelines and competencies
- and salaries/rewards. [51]

Allied health professionals in ICU

Ella Terblanche, Jackie McRae, Sarah Dzumbira and Paul Twose

Introduction

In 1984, it was quoted that ‘the success of intensive care is not therefore to be measured only by the statistics of survival, as though each death were a medical failure. It is to be measured by the quality of lives preserved or restored and by the dying of those in whose interest it is to die and by the quality of the human relationships involved in each death’. [1]

Over 40 years on there is ever-increasing evidence that survivors of critical illness are at risk for post-intensive care sequelae including physical and cognitive impairments, mood disorders, fatigue and frailty. [2] Based on this understanding, the last 2 decades have seen increasing recognition of the roles, contributions and value that allied health professionals provide within intensive care, especially in their focus on recovery and rehabilitation. [3] Each allied health professional (AHP) profession provides its own unique contribution both directly and indirectly to patient care but is grounded in its approach to provide holistic, patient-centred and multi-professional services. This model of care locates the patient centrally in the professional relationship and supports the notion that an understanding of the patient’s perspective should underpin good practice in an equal therapeutic relationship. [4]

Publications have highlighted the role of individual allied health professions (dietitians, occupational therapists [OTs], physiotherapists [PTs] and speech and language therapists [SLTs]) in providing specialist intervention to those requiring intensive care. [5], [6] More recently, focus has been placed on the combined contribution that these professions provide and the clear overlap in the ways of working, with significant contributions to strategic direction, education, continuous quality improvement and research. [7]

The importance of AHP's working within intensive care unit (ICU) has also been highlighted in UK national guidelines focusing on both the provision of intensive care services and the recovery of those patients requiring intensive care. The 2009 National Institute for Health and Care Excellence (NICE) guideline [8] for rehabilitation after critical illness was paramount in raising the profile of rehabilitation and recovery services during and after critical illness and has subsequently been further supported by the NICE quality standards for rehabilitation after critical illness in adults, [9] Life after Critical Illness [10] and the Guidelines for Provision of Intensive Care Services. [11]

This chapter will provide an overview of the unique contributions of four AHP professions (dietetics, occupational therapy, physiotherapy and speech and language therapy) and utilise a patient case study to demonstrate the benefits of the multi-professional approach to rehabilitation and recovery services for those requiring intensive care.

Dietetics

Patients in critical care for more than 48 hours are likely to be at high risk of developing malnutrition. [12] Most require enteral, parenteral, or oral nutrition support (or a combination of these) to meet their nutritional needs and the provision of this nutrition support is challenging and complex. The use of early enteral nutrition (EN) is favoured, usually initiated by a nurse or doctor-led protocols. [12] The European Society for Parenteral and Enteral Nutrition guidelines recommend a progressive and stepwise increase in nutrition delivery followed by individualisation of energy and protein targets, with the aim of reducing the risk of malnutrition and avoidance of overfeeding and nutrition-related complications. [12] Progressively over the last 30 years, the dietitian has become commonplace in the ICU multi-professional team (MPT) providing unique nutrition knowledge, clinical expertise and skills in this setting gained from their dedicated training in nutrition and dietetics. [7, 13]

Individualised Nutrition Treatment Plans

The primary role of the dietitian is to provide individualised nutrition treatment plans in partnership with clinicians, patients and carers. [7] Up to 78% of patients present to ICU malnourished, [14] and this is associated with a significant increase in mortality, longer ICU stays and ICU re-admissions. [14] Dietitians use a combination of assessment tools and clinical skills to identify patients who are malnourished and implement appropriate nutritional treatment plans. [7, 13, 14] This includes setting energy and protein targets, undertaking and interpreting indirect calorimetry, advising on the most appropriate nutrition regimen and ongoing monitoring. They assess and take account of the many factors influencing the nutrition support treatment plan and provide ongoing monitoring throughout the ICU admission. Considerations include age, diagnosis, comorbidities, illness severity, organ failures, projected length of stay, gastrointestinal function and critical care treatment modalities, drug-nutrient interactions, metabolic complications, electrolytes for risk of refeeding syndrome and glycaemic control. [7, 13, 15] In studies where dietitians provide individualised nutrition treatments to ICU patients EN is initiated earlier and an increase in nutrition delivery is observed. [16]

Bedside insertion of enteral feeding tubes, especially jejunal tubes by advanced practice dietitians has led to cost savings by avoiding x-rays, reducing endoscopy referrals and the need for parenteral nutrition and minimising feeding delay and reduction in EN interruptions. [17, 18]

Research and Education

Dietitians frequently appraise and disseminate the findings of nutrition research and are thus best placed to lead the development and implementation of local unit nutrition guidelines. Their ongoing education of the MPT results in improved protocol compliance and associated increased nutrition provision. [19-21] Bespoke protocols for reducing fasting times in ICU designed by dietitians, result in a significant reduction in the time EN is withheld and enhanced nutrition provision. [22] In a large multicentred international study, the greater number of funded ICU dietitians was significantly associated with better provision of nutrition support and earlier initiation of EN in line with international ICU nutritional guidelines. [21]

Ongoing Care

After extubation, patients can experience a multitude of barriers to adequate nutritional intake such as poor appetite, dysphagia, taste changes, early satiety and gastrointestinal dysfunction ultimately leading to malnutrition. [23] This impacts recovery and rehabilitation which relies on adequate nutritional intake. Dietitians, provide ongoing nutritional treatments, including supplementary EN or oral nutrition supplements, playing a fundamental role in the nutritional rehabilitation of survivors of critical illness.

Occupational therapy

Occupational therapy (OT) within critical care remains a new emerging AHP discipline. Occupational therapists are uniquely dual trained to assess occupational performance issues which impact a patient’s physical or mental health. Nationally, OT input in critical care remains variable, resulting in inequitable coverage. However, the impact of the COVID-19 pandemic has highlighted the value of OT, and increasingly funding has been supported to provide an OT service in ICUs. Early occupational therapy input within an ICU environment has demonstrated timely OT intervention not only decreases the number of bed days in ICU but the entire acute hospital admission duration; there is a growing body of literature [12-14] that OT intervention can improve quality of life and long-term outcomes. The role of the OT in intensive care can best be summarised into three key areas of practice [24] ; early rehabilitation, cognition and intensive care recovery clinic.

Early Rehabilitation

Within the scope of early rehabilitation, OT plays an imperative role in early engagement in meaningful occupations, and avoidance of occupational deprivation within the ICU. OT assessment and intervention could include facilitating leisure activities such as iPad use/colouring and with personal activities of daily living (ADLs) such as brushing their teeth or hair and washing their face. Other aspects of the early rehabilitation role for OT involve rehabilitation for intensive care unit acquired weakness (ICU-AW), upper limb therapy/management, 24-hour postural management, splinting, oedema and visual assessment. Occupational therapists will also work alongside their physiotherapy colleagues, to complete assessments through postural sets using specialist therapeutic handling, which will inform the need for further specialist postural/seating assessment and/or specialist wheelchair provision. This forms an important part of early rehabilitation as it facilitates increased awareness and functional engagement of their environment. A seated position can facilitate progression in the respiratory and tracheostomy weaning process due to improved respiratory mechanics.

Cognition

Occupational therapy brings a unique skill set to the assessment of cognition within the ICU. Increasingly, the MPT is beginning to understand the long-term impact delirium can have on ICU survivors’ physical, psycho-social health and quality of life. OT can support a bespoke orientation programme, through specific orientation exercises and supporting to establish meaningful routine/structure, aiding in re-orientating a patient to the present. Furthermore, OT intervention is essential for those in the ICU who experience a brain injury (stroke, out-of-hospital cardiac arrest or hypoxic brain injury etc.). National guidelines state that assessment and cognitive rehabilitation, form an imperative part of ongoing recovery. Furthermore, there is an identified need for OT in the specialist assessment of disorders of consciousness, best interest process and development of a sensory integration stimulation programme.[11, 25]

Intensive Care Recovery Clinics

The UK Faculty of Intensive Care Medicine guide ‘Life after Critical Illness’ indicates that nationally only 21% of intensive care recovery clinics have an occupational therapist as part of the MPT. [10] Occupational therapists bring immense value to the post-ICU caseload as they provide expertise in impairments of occupational performance and can support with re-establishing occupational balance/routine, an assessment of cognitive impairment, fatigue management and pacing, sleep hygiene, motivation and volition, goal setting, and social prescribing and onward referral to community services. Finally, occupational therapists support vocational rehabilitation in aiding ICU survivors with bespoke interventions to work towards a return to paid employment. [24]

Physiotherapy

Physiotherapy is one of the principal and most consistent AHP services for intensive care. [11] From its early origins in maintaining bronchial hygiene for people who were spontaneously breathing or intubated, to its current focus on early mobility and physical recovery, physiotherapists provide vital input both within the ICU and across the recovery continuum. [26]

Across the United Kingdom, access to physiotherapy for patients in ICU is provided 24 hours a day, 7 days a week, and is achieved through the provision of out-of-hours or on-call services and weekend working. [11] Recent surveys have demonstrated that 100% of ICUs in the United Kingdom have input from physiotherapy although the quantity of input is variable, with different staffing and funding models. [7] Physiotherapists are also increasingly involved in intensive care recovery clinics and post-intensive care rehabilitation programmes, with evidence showing increased availability of these services. [27]

Respiratory Care

Respiratory dysfunction secondary to either failure of ventilatory mechanics or ineffective gas exchange is one of the most prevalent causes of admission to the ICU. These patients are at high risk of secretion retention and atelectasis. [28] There risks are further heightened by the need for intubation and mechanical ventilation.

Physiotherapy aims to enhance airway secretion clearance, optimise lung volume and improve oxygenation, and reduce airway resistance and work of breathing. Through a variety of techniques including positioning; manual techniques; augmented airway clearance (e.g. mechanical insufflation-exsufflation (MI-E); manual and ventilator hyperinflation; and tracheal suction, respiratory physiotherapy aims to minimise respiratory complications, and in conjunction with early mobilisation, reduce requirement and duration of mechanical ventilation and overall length of stay within ICU. [29]

In conjunction with speech and language therapy and the wider multi-disciplinary team, physiotherapists are also involved in the management of patients requiring a tracheostomy including providing expertise in tracheostomy weaning and supporting decannulation decision making. [30]

Early Mobility and Rehabilitation

Since the early 2000s and the introduction of national guidelines for rehabilitation after critical illness, rehabilitation has become an integral component of physiotherapy practice within the ICU. Physical rehabilitation aims to target the effects of ICU-AW and reduce the impacts of post-intensive care syndrome, by providing a seamless transition of rehabilitation delivery for patients across the recovery pathway, commencing at ICU admission and continuing to recovery in the community. [27]

Early mobility or rehabilitation within the ICU refers to the provision of physical activity provided to critically ill patients following the achievement of clinical stability. Time from ICU admission to administration of early mobility is suggested to be within the first 48 hours although further research is required to establish the feasibility of this approach. These interventions are widely safe and feasible, with expert consensus-driven algorithms developed across Australia and North America to support clinical decision making. [31]

Systematic review evidence, trial data and quality improvement projects have shown that patients derive short-term benefits from physical rehabilitation delivered in the ICU, including improved physical function, quality of life and reduced lengths of stay in ICU and hospital. [3] These improvements are achieved through the progression of increasingly functional activities and more recently the use of cycle ergometry and electrical muscle stimulation. [26]

Speech and Language Therapy

Speech and language therapists (SLTs) in the United Kingdom have developed expertise in the evaluation and treatment of speech, swallowing and airway impairments in ICU patients, specifically those requiring tracheostomy and ventilation, over the last 20 years. [32] There is growing clinical and research evidence of the disruption of these interventions on the anatomy and physiology of the larynx, pharynx and oral structures, in addition to any primary impairment. [33]

Communication

The ability to talk provides patients with agency and control over their environment, enhancing their experience and ability to contribute to their rehabilitation and reduce the impact of delirium. Intensive care patients may experience a disruption to voice production, articulation or language skills. SLTs will evaluate speech and language skills and support early attempts to communicate basic needs whilst providing specific rehabilitation to improve identified impairments. [34]

Secretion Management

Many ICU patients with a tracheostomy can experience high oral secretion loads, which may be linked to reduced frequency or effectiveness of swallowing function. This often limits cuff deflation and decannulation, delaying rehabilitation progress. Alongside physiotherapy colleagues, the SLT can evaluate the nature of the impairment and deliver an intervention focused on strengthening and improving swallowing skills to help reduce excessive oral secretions. This reduces the suction need and facilitates progress towards decannulation. It is important to consider regular mouthcare, maintain oral hygiene and manage issues with thirst through a programme of oral moisturisation.[35]

Oral Intake

Eating and drinking are key quality-of-life factors. Patients often feel despondent when they are diagnosed with a swallowing impairment (dysphagia) and are restricted in their oral intake. ICU patients are especially vulnerable to silent aspiration if they have been intubated and require a tracheostomy, as this can damage the sensitive laryngeal mucosa and disrupt the swallow-breath cycle known to modulate swallow timing and airway safety.[36] SLT-led instrumental assessments, such as flexible endoscopic evaluation of swallowing (FEES) are essential as early diagnostic tools to identify impairments and plan swallow rehabilitation with clear progression back to oral intake. Patients benefit most from regular speech and language therapy interventions with increased intensity that build swallowing skills and strength. Diet modifications can be used as compensation for specific impairments, for example, thickened fluids are used to compensate for reduced oral transit and delayed swallow initiation for thin fluids, however, they are not suitable for patients who have reduced pharyngeal clearance as this can increase stasis and consequently, risk of aspiration.[36] All swallow strategies and texture modifications should be evaluated using instrumental assessments prior to commencement to ensure risk is minimised.

National UK guidance documents[9,11,37,38] see the role of SLT as being integral to delivering rehabilitation in intensive care, with a reduction in complications and lengths of stay alongside improved outcomes for communication and swallowing.[39,40] Training to develop SLT critical care skills takes place post-registration and is often reliant on work-based training and supervision that aligns with competency frameworks.[41,42]

Minimum standards have been set for ICU-based SLT services to ensure a rehabilitation ethos:

- Advanced practice in the assessment and evaluation of laryngeal function using instrumental tools such as FEES, alongside newly emerging technology such as surface electromyography, ultrasound and neuromuscular electronic stimulation.
- More than one SLT to ensure cover during leave. Planning and delivery of bespoke interventions to address impairments.
- High levels of skill and training with regular supervisory support.
- Integration with the multi-disciplinary team to make joint decisions and plan rehabilitation timetables.
- Use of validated outcome measures to track changes at baseline and discharge as a result of interventions.

Case study

A 35-year-old male is admitted to a major trauma unit following a road traffic incident and has a displacement of the cervical spine resulting in a cervical level spinal cord injury. The patient is intubated and ventilated and undergoes spinal surgery. Post-operatively, he has a tracheostomy and continues to be ventilated but no longer requires sedation. He attempts to communicate but is unable to use his voice due to the tracheostomy cuff being inflated. His level of injury means that he has no upper limb function, so cannot access alternative communication aids. It is difficult for the team to know if his communication attempts make sense.

Early physiotherapy input has involved strategies to prevent secretion retention and, because of the muscle weakness and reduced cough strength, has included the delivery of mechanical insufflation-exsufflation or cough assist. This has been delivered initially via the endotracheal tube and now the tracheostomy tube. Physiotherapy input has also been provided to maintain joint range of movement, with early use of splints to maintain foot and ankle position and to provide positioning advice to the wider MPT to reduce the potential of secondary damage as well as aid secretion clearance and reduce work of breathing.

The SLT on the team is asked to see him and help with communication. Using simple yes/no questions, the SLT can ascertain that he understands simple questions and is making a request about a family member. The SLT has access to electronic communication aids that use eye pointing to indicate communication intent. They try this with the patient but it is too effortful. As speech is the quickest and most effective form of communication, the team discussed options. Whilst requiring high levels of ventilation, the cuff needs to remain inflated so above-cuff vocalisation is considered. To check for any contra-indication and laryngeal pathology, the SLT arranges a flexible nasendoscopy, which can also show any structural or neurological impairments affecting saliva management and swallowing. A trial can be undertaken to evaluate sensory and motor response to this alternative airflow. There is some narrowing of the glottis in response to the airflow and brief phonation is achieved. Short trials are arranged to provide an opportunity for speech, whilst the team continues to work on weaning from ventilation by lowering pressures.

Once a pressure support of 10 to 12 cm H_2O and a PEEP <8 cm H_2O is achieved, the team decides that cuff deflation can be trialled. The patient briefly shows some discomfort as secretions are cleared and then his voice emerges, and he is delighted to be able to talk. This is tolerated well for 5 minutes, and a regime of regular cuff deflation is added to the rehabilitation regime. Over the next 2 weeks, cuff deflation is tolerated for 2 hours, and swallowing trials can commence. Again, to evaluate motor and sensory responses a FEES is done with food trials to ascertain the safest texture and quantity.

A nasogastric feeding tube (NGT) is inserted for nutrition provision. Initially, this was started using the ICU feeding protocol. After 72 hours from admission, he is assessed by the ICU dietitian and an individualised feeding plan is provided taking into consideration his age, sex, weight, height, diagnosis and critical care treatments. He is experiencing large gastric residual volumes so the dietitian liaises with the medical team to get prokinetic agents commenced. On day 5 the dietitian performs indirect calorimetry to measure his resting energy expenditure and to best guide his energy targets. It suggests he requires an additional 300 kcal a day. Also, at this time he is on a high infusion rate of propofol, and as it comes in a lipid solution providing 1.1 kcal/mL, the feeding plan is adjusted to take this into consideration, avoiding overfeeding in the early phase of critical illness. A high protein, fibre-containing feed is used. The fibre will help with maintaining the gut function, along with a spinal bowel management plan of daily enemas and laxatives. After the first few weeks, the dietitian and SLT work closely together regarding swallowing trials and the anticipated swallowing trajectory. If commencing an oral diet seems unlikely following the FEES assessment, early discussions regarding the insertion of a longer-term gastrostomy feeding tube are indicated. If oral intake is commenced, the dietitian will monitor the amount taken and reduce the NG feed accordingly to supplement intake, often done overnight to allow the patient to eat and drink freely during the day.

The dietitian liaises regularly with the physiotherapist and occupational therapist to understand how much activity and rehabilitation is being undertaken and adjusts nutrition targets to reflect this. Once the NGT is removed, the use of oral nutrition supplement drinks is likely to help the patient fully meet his nutritional targets for ICU recovery.

Once the patient has a voice, they present with evidence of confusion. A confusion assessment method for ICU (CAM-ICU) score is completed which indicates a positive score for delirium. The OT also supports the MPT to establish that the patient presents with hypo-active delirium. A daily orientation programme is established and familiar personal items are brought to the bedside to assist with re-orientation and support with sleep hygiene and normalising sleep-wake cycles, utilising non-pharmacological methods. With a more normalised sleep-wake cycle, the OT completes a formalised cognitive assessment via an orientation-log assessment. The OT works with the patient’s caregivers to ascertain a detailed personal social history.

A personal social history supports physiotherapy, OT and SLT to develop a personalised early rehabilitation programme and set goals which engage and motivate the patient. A full upper limb assessment is completed and a 24-hour postural management programme including upper limb splinting is recommended to maintain joint range and prevent contractures. The OT works jointly with the SLT to establish alternative access to a call bell so that the patient can call for help using an *jellybean-switch.

The OT completes a postural assessment and liaises with the nursing staff to ascertain the patient’s pressure care needs. A seating assessment is completed jointly between the OT and physiotherapist in a tilt-in-space wheelchair. This seating provides trunk and head support and facilitates the ability for the patient to access the ICU garden with their family and nursing team for the first time.

The patient continues to receive input from the allied health professionals (AHP) team within critical care. All members of the team, in conjunction with the wider multi-disciplinary team and the patient, continue to regularly set rehabilitation goals. These focus on weaning from mechanical ventilation and tracheostomy, as well as focusing on functional rehabilitation. Once the patient becomes appropriate for transfer to the ward, the AHP team will provide a detailed summary to colleagues on the acute ward and provide the patient with their own individual treatment plan.

Summary

AHPs form an essential component of the critical care MPT. AHPs work collaboratively to provide early intervention to patients admitted to critical care and will continue to provide input across the recovery pathway. Each allied health profession has its own unique knowledge and skills which are essential to patient care, with a particular focus on rehabilitation and recovery.

Team-based healthcare delivery

Laura Vincent and Gerry O'Callaghan

Introduction

The concept of health professionals working in collaboration as part of multidisciplinary teams, focused on the requirements of individual patients, is a well-established historical tradition. [1] This chapter outlines the benefits of team participation to the consumer, clinician, team and healthcare delivery organisation (unit, department and hospital). The characteristics of successful teams and examples of effective team-based interventions are described in the context of intensive care medicine or comparable acute care settings. Specific interventions that have been applied in the intensive care setting, team composition, function and effect on patient outcomes are explored. The objective of this overview is to provide practitioners of intensive care medicine with an opportunity to reflect on the variety of ways we work in teams as part of our daily professional activities.

What Is a Team?

Shared purpose is the foundation of team success. [2] A team is defined as a group of people with clearly defined roles and responsibilities, committed to a common purpose or task. Individuals who participate in an effective team share common values and commit to shared behaviours. The result of their collective effort is expected to produce more than they could deliver as individuals. The identity of the team is visible from both within and outside (Box 5.1).

Box 5.1

Characteristics of a team

Common goals
Shared behaviours and values
Visible identity
Clear understanding of roles and responsibilities
Greater collective effectiveness or potential than individual
Understanding of shared tools and artefacts, such as vocabulary, skills and knowledge
Mutual trust and respect: solidarity

Modern intensive care medicine is a challenge of both skill and endurance, the latter increasingly described as resilience. Relative to decades of investment in education and training focused on required knowledge, we have only recently begun to interrogate the most effective strategies for the sustained translation of this knowledge (evidence) into practice. Specifically, what workplace characteristics and evidence-based practices are of greatest benefit to both patients and practitioners? The increasing array of investigations and complex treatments for critical illness is accompanied by increases in both the number and diversity of team members as defined by their roles, functions, disciplines, professions or specialties; in this context, it is useful to understand the fundamentals of team dynamics. Additional factors are new roles and scopes of practice for non-physician providers and participation by intensive care clinicians in roles that extend beyond the traditional physical boundaries of the intensive care unit (ICU). The introduction of advanced practice nursing and other emerging roles has led to a deeper understanding of the competencies necessary to adopt team-based practices. [3] A thorough review of the clinical and non-technical skills required in a specific service delivery context is critical before adopting team-based programmes on a significant scale.

Fig. 5.1 illustrates the diversity of individuals and skills involved in caring for critically ill patients. ICU personnel include medical and nursing professionals, and allied health disciplines including physiotherapists, respiratory therapists, dieticians and pharmacists. Support personnel include clerks, cleaners and others. External ICU is almost limitless including physicians, surgeons, infectious disease physicians and radiologists. Although local factors influence the composition and profile of these categories, the variety, turnover and complexity are constant. Boltey and colleagues have recently provided contextual insights by differentiating between the broader collaborative context in which critical care teams function, which has a high degree of team instability and more stable outcome-oriented teams, which pursue clear strategic or operational goals within this clinical microsystem. [4] Through a series of observational studies and interviews, they described ways of working that facilitate collaboration as well as the behaviours used to directly collaborate (Box 5.2). Most interactions in an ICU environment are more correctly described as interprofessional collaboration, within which smaller groups engage in team-based actions to achieve clear outcomes. The implication from this insight is for organisations to proactively create an environment of conscious collaboration at a clinical microsystem or whole-system level using policies, procedures, governance structures and education which support effective team behaviours (see the section ‘Organisational Change’).

Dietician

The diagram consists of two concentric circles. The inner circle contains the word patient at the centre. The surrounding outer circle includes labels of healthcare and support roles positioned around the central circle. These roles include cleaners, respiratory therapist, allied health, specialists, residents, nursing, speech pathology, dietician, social worker, physiotherapy, occupational therapist, and pharmacists.

FIG. 5.1 The clinical and ancillary care of patients in intensive care is provided by large diverse teams of health care workers. The size, diversity, variability and complexity of these teams make common training in non-technical skills highly desirable.

Box 5.2

Process of inter-professional collaboration

Enablers (ways used to facilitate collaboration)	**Activities (behaviours used to directly collaborate)**
Active listening	Correction
Approach, validation	Fill in the gap, troubleshoot
Coordinate work	Teach/train
Intra-professional consult	Information exchange
Invitation, send page, call	Provide help
Nonverbal and verbal accessibility	Socialising
Reflexive question	Negotiation

From Boltey E, Iwashyna T, Cohn A, Costa D. Identifying the unique behaviors embedded in the process of interprofessional collaboration in the ICU. *J Interprof Care* . 2023;37(6):857–865. https://doi.org/10.1080/13561820.2023.2202218

The composition of critical care teams has wide regional, national and international variability. Non-physician providers are more common in North America than in the United Kingdom, Europe or Australia, where advanced nurse practitioner roles are more common. Such roles are well established in paediatric and neonatal medicine and are often an adjunct rather than an alternative to physicians in training, resulting in improved staffing levels and continuity of patient care. More than a quarter of adult academic ICUs in the United States have physician assistants, and more than half have nurse practitioners. [5] They have a precisely defined scope of practice, may order tests, prescribe medications and perform diagnostic and therapeutic procedures under supervision or on behalf of a nominated responsible physician or surgeon. In a review of the impact of non-physician providers on patient outcomes in critical care, there is evidence that non-physician providers decrease hospital mortality and length of stay and positively impact physician education.[6] Non-physician providers also contribute important increased capacity in additional areas of intensive care activity, such as quality improvement.[7] Current workforce challenges indicate this is likely to remain the case for the foreseeable future.

The increasing diversity of clinical roles and complexity of therapies (e.g. extracorporeal membrane oxygenation) require frameworks for effective communication, role delineation and care coordination. This view has been endorsed for over a decade by a wide range of professional, academic and government bodies, such as The Institute of Medicine, which recommended in ‘*To Err is Human, Building a Safer Health System*’ that those who work in teams should train in teams.[8] There is an emerging literature that demonstrates improved outcomes across a range of parameters following the implementation of various team-based interventions.[1] These interventions are examined later in this chapter.

Fig. 5.2 illustrates the varying and often asynchronous schedule of shift changes between nursing, resident and intensive care physicians challenging safe and effective continuity of patient care. The situation–background–assessment–recommendation (SBAR) approach to clinical handover is an early example of a shared behaviour to improve communication; it is an explicit team-based practice that facilitates continuity of care and effective transfer of information.[9] Other early examples of widely adopted team-based behaviours are the use of checklists, protocols, huddles and briefs.[10] The process of developing and implementing these common ways of working requires multidisciplinary collaboration and creates a shared sense of purpose and team identity.

Continuity of patient care

The labelled diagram presents a horizontal arrow representing the continuity of patient care, progressing from admission on the left to home on the right. The starting point is a rectangular box labelled admission. Moving right, two vertical lines labelled E D team and operating room are positioned before a large rectangular section titled patient journey. Within this section is another box labelled specialist I C U, which contains repeated labels of R N under headings for resident doctors on both the left and right. Below the left segment is a label for allied health. After the specialist I C U segment, the timeline continues with two additional vertical lines labelled ward and rehab. The arrow terminates at a rectangular box labelled Home. The layout visually represents a continuous path through multiple care stages involving healthcare professionals and medical environments.

FIG. 5.2 Continuity of patient care is the seamless provision of care, transfer of information and communication with relevant stakeholders over time and across multiple locations during a patient's hospitalisation or illness. *ED* , Emergency department; *ICU* , intensive care unit; *RN* , registered nurse.

Team Stability

Frequent personal interactions are unavoidable in the dynamic inter-professional collaborative microsystem of an ICU given the nature of rostering requirements, professional diversity, education and training pathways and safe work practices. Workplace characteristics which increase clinician engagement such as high-quality education, training, participation in research and merit-based professional development reduce turnover and improve attraction and retention rates, positively contributing to team stability and reduced costs. [11] Organisations which take a multifaceted structured approach such as the Magnet programme optimise working conditions by proactive measurement of patient satisfaction and workplace culture, involvement of workforce in decision-making and career development, with benefits in attraction and retention of nursing workforce, reduced sick leave and improved patient outcomes. [12] Team stability has been demonstrated to improve a range of outcomes across a range of complex surgical contexts with significant reductions in procedure time, cost and infections associated with teams who are familiar with their work environment and each other. [13] These findings are likely applicable in ICU concerning complex task-based interventions and should provoke consideration of rostering practices.

Costa and colleagues performed a network analysis of nurse rostering practices across two large ICUs using the concepts of *coreness* , high-frequency team interactions as a marker of efficient coordination of care, and *betweenness* , high-frequency interactions across multiple teams as a marker of ability to receive and disseminate useful information. [14] This study demonstrated improved mortality outcomes for patients who had more exposure to both nursing cohorts. Both studies provide excellent templates for further research across multiple sites to assess relevance to the ICU environment.

Patient safety is the main driver for adopting team-based interventions in healthcare similar to improvements in passenger safety achieved by the airline industry using a team training approach called crew resource management (CRM), a simulation-based programme that teaches and assesses the individual performance of the ‘non-technical skills necessary for effective delivery of complex technical tasks in high-stress situations’. These can be defined as ‘the cognitive, social and personal resource skills that complement technical skills, and contribute to safe and efficient task performance’. [15] The framework has four elements:

- *Situation awareness:* Understanding and anticipating the impact of the specific situation on the performance of workers and patient outcomes. For example using clarifying questions or check-back to validate important information.
- *Decision-making:* The ability to identify options, incorporate risk assessment and re-evaluate progress, recognising failure and changing direction in a timely way.
- *Teamwork and leadership:* Cooperative collaboration in complex task delivery in your assigned role; explicitly identify and claim the role that is appropriate to your level of skill and experience. This includes information sharing, seeking assistance, supporting fellow team members and coordinating efforts.
- *Task management:* Planning, preparing and prioritising the actions that need to be taken, identifying the resources necessary to achieve the planned tasks and performing them to an appropriate standard.

A training programme based on this approach has been developed for anaesthetists called anaesthetists' non-technical skills (ANTS). Extensive task analysis, describing the language and behaviours specific to situations encountered by anaesthetists, formed the basis for identifying markers used for the assessment of good or bad performance [16] (Box 5.2).

Process of Inter-professional Collaboration

The quantity and quality of team interactions can be measured and team behaviours and patterns of communication are consistent across different contexts and compositions (i.e. different industries including healthcare and a variety of different team sizes). [17]

Successful teams consistently demonstrate the following characteristics:

- Leaders encourage participation

- Effective decision-making; clear, transparent, timely and consultative
- Open and clear communication
- Diversity of experience, gender, age, culture and knowledge
- Mutual trust, committing to shared actions
- Managing conflict – dealing with conflict openly and transparently, avoiding the gradual build-up of internal tensions and grudges
- Clear goals that have personal meaning and relevance, supported by sharing data and resources
- Defined roles and responsibilities – team members understand what they must and must not do
- Coordinative relationship: strong bonds between team members supporting frequent interactions

Necessary Characteristics That Support Effective Improvement in Clinical Practice and Patient Outcomes

For team-based interventions to positively contribute to patient safety and the well-being of healthcare workers, the host organisation (usually a hospital or health service) needs to be receptive. Such an environment aligns leadership support at all levels consistent with the organisation’s strategic goals, has well understood and accepted models of change, which include consumers in design and allocate resources to areas of priority. In addition, there is an appreciation by leaders of:

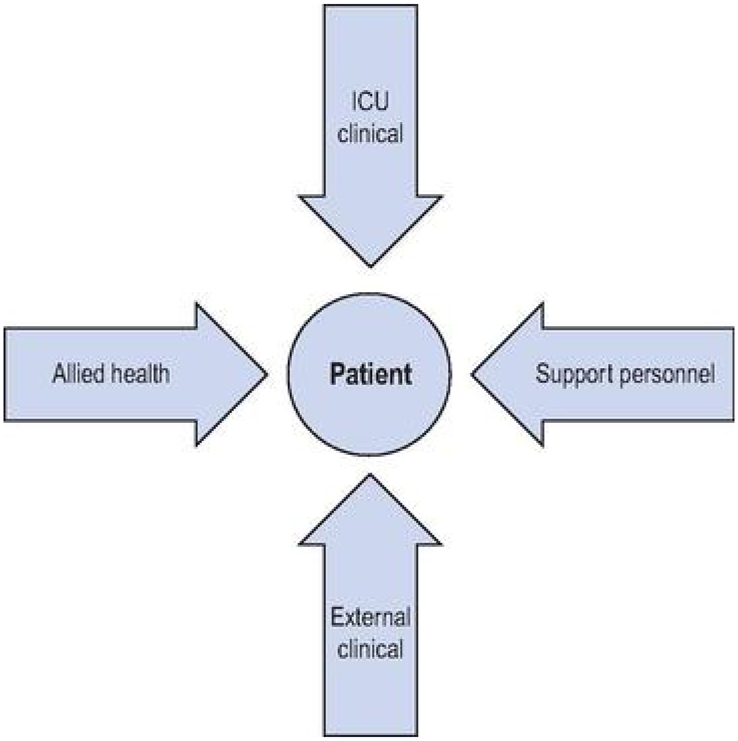
- The resolve, expertise, timeframes and resources required to achieve cultural change
- The importance of advocacy for team-based training and inter-professional practice
- The provision of sufficient time, opportunity, resources and executive support.

Bohmer characterised the four habits of high-value healthcare organisations that perform well in terms of the ratio of long-term outcomes to costs [18] :

1. *Specify and plan in advance:* with decisions based on predetermined explicit criteria
2. *Deliberate design of infrastructure:* including clinical microsystems that align physical environment, business process and clinical pathways in well-defined patient populations
3. *Measurement and oversight targeting:* by predefined metrics, quality and safety goals, which inculcates both accountability and performance
4. *Self-study:* using measurements so that knowledge, data and clinical information can be used, not only for the assurance of best evidence-based practices, but also to identify variation. Information is shared and not considered to be the property of individuals or departments.

Types of Team

A *clinical microsystem* is the most fundamental unit of health care delivery that addresses the needs of a population of patients. It is the dynamic integration of personnel, clinical and support staff, technology, information, clinical and business processes.[19] The participation of all those who have direct patient care responsibilities is implicit and compulsory (Fig. 5.3). Most participants will be involved in multiple team types within this structure. The discretion of individuals within teams is variable. The greater the clinical focus of the team or activity, the less choice individuals have in terms of choosing to participate. Resuscitation, diagnosis and treatment are core team activities, while research, safety and quality and administration provide an opportunity for discretion that aligns with the interests and expertise of the individual. Collaborations beyond the immediate clinical microsystem in professional, interdisciplinary and academic activities have the greatest degree of autonomy. This broader collaborative environment supports effective team development to pursue specific goals focused on patient outcomes or alternative professional achievements such as research or education.



The diagram consists of four large arrows pointing inward toward a central circle labelled patient. The top arrow is directed downward and labelled I C U clinical. The bottom arrow points upward and is labelled external clinical. The leftward arrow is labelled allied health, and the rightward arrow is labelled support personnel.

FIG. 5.3 Clinical microsystems are the most fundamental units of health care delivery that address the needs of a specific population of patients. This system includes personnel, procedures, business processes and infrastructure. *ICU* , Intensive care unit.

Critical Incident Response Teams

Medical emergency, code and trauma teams need skills designed to meet the crisis, such as vascular access, airway and trauma management. Teams may be nurse or physician-led, are highly focused on a particular activity, and often include individuals who interact infrequently owing to the rarity of certain events or rostering practices. Team membership is highly dynamic; opportunities for training are limited; and the level of familiarity with local procedures, policies and organisational characteristics varies with the individual team member (Fig. 5.4).

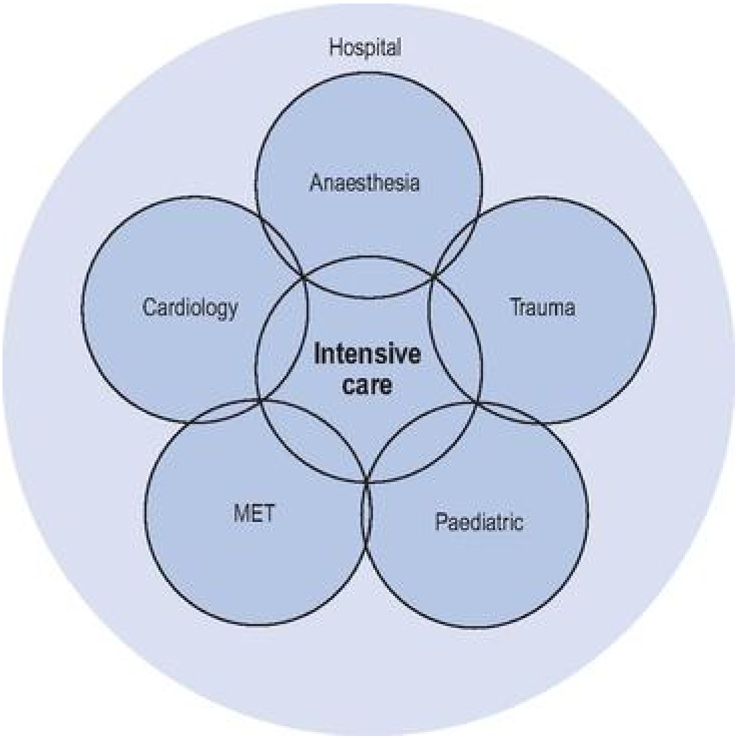
Continuity of patient care

The diagram presents two intersecting axes. A horizontal arrow labelled continuity of patient care extends from left to right, beginning at a box labelled admission and ending at a box labelled home. Along this path are vertical markers labelled E D team, operating room, ward, and rehab. At the centre of the path is a rectangular area labelled patient journey, containing two adjacent sections titled resident doctors. Each section includes three smaller boxes labelled R N. Below these sections is a horizontal box labelled specialist I C U, which contains a subsection labelled allied health. Perpendicular to the horizontal axis is a vertical arrow labelled hierarchy of engagement. It begins at the admission box and continues upward through a box labelled clinical microsystem, reaching a final box labelled community of practice. A dotted diagonal arrow extends from the clinical microsystem toward the upper right, labelled increasing personal choice and autonomy. The layout presents the progression of care and engagement through multiple levels of clinical involvement.

FIG. 5.4 The hierarchy of individual integration of team participation represents the relationship between the interests and skills of an individual and the necessary activities that support a clinical microsystem, such as an intensive care unit (ICU). Activities that are not directly related to patient care provide an opportunity for personnel to choose those activities that are of greatest professional interest. *ED* , Emergency department; *RN* , registered nurse.

Leadership by an easily identifiable authority figure, who has both accountability and responsibility for the outcome, enables the application of shared mental models such as well-defined clinical pathways or protocols. This leadership is variously described as top-down or transactional and has been demonstrated to improve both process metrics and patient outcomes [20] (Fig. 5.5).

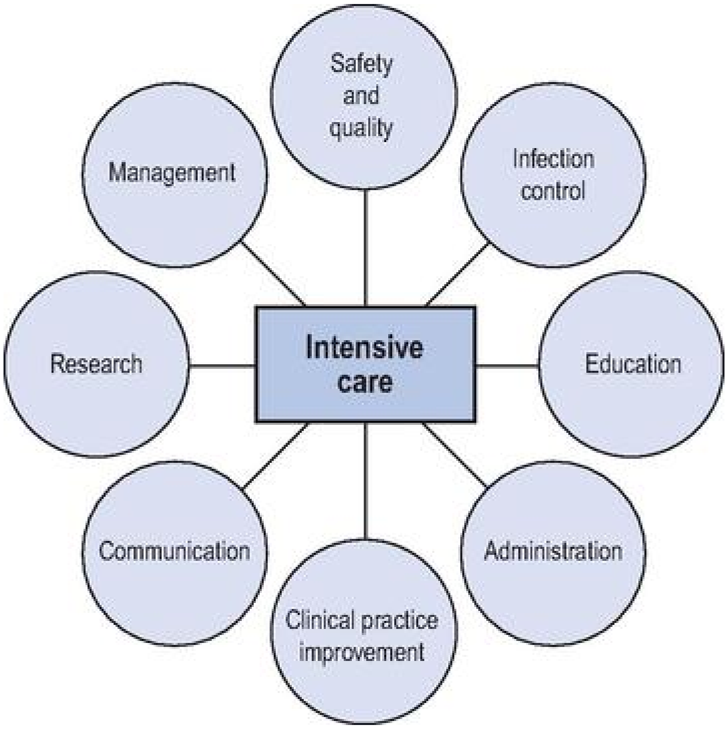


The diagram consists of a large outer circle enclosing six smaller overlapping circles arranged in a radial pattern around a central circle labelled intensive care. The surrounding circles are labelled hospital, anaesthesia, trauma, paediatric, M E T, and cardiology. Each of the six circles intersects with the central intensive care circle and overlaps slightly with adjacent circles, forming a continuous cluster.

FIG. 5.5 Critical incident teams are ad hoc teams of individuals from a range of clinical and professional backgrounds that assemble to meet the clinical needs of a patient experiencing acute physiological deterioration in an acute hospital setting. *MET* , Medical emergency team.

Activity- or Context-Related Teams

These may be described as committees, working groups or parties with variable degrees of formality and stability. These range from informal groups of volunteers to formal safety and quality committees with clear reporting protocols and accountabilities. The latter has defined terms of reference, meets regularly, involves clinical governance, keeps records and may be multidisciplinary from both within and outside the ICU. They may be temporary, such as implementing a new treatment, or consist of well-established groups responsible for monitoring and communicating clinical outcomes to their peers on a range of clinical indicators. Fig. 5.6 illustrates examples of such clinical contexts.



Safety and quality
Infection control
Education
Administration
Clinical practice improvement
Communication
Research
Management
Intensive care

The diagram features a central horizontal rectangle labelled intensive care, connected by straight lines to eight surrounding circles arranged radially. The top circle is labelled safety and quality. Moving clockwise, the other circles are labelled infection control, education, administration, clinical practice improvement, communication, research, and management.

FIG. 5.6 Context- or activity-based teams are comprised of individuals from a range of clinical and professional backgrounds who are collectively engaged in administrative, educational and professional activities that support clinical care.

Critical incident and context teams benefit from different styles of leadership. Leadership characteristics include inclusiveness, proactive mentorship of less experienced or confident team members, modelling of ethical practice and maintaining the focus of team members on the shared goal or purpose. This type of leadership is variously described as democratic, consensus-driven or transformative and is associated with improved staff commitment and participation in safety initiatives. The challenge is choosing the most appropriate leadership style for each situation. Adaptive leadership is the capability to move between a transactional approach for task-based time-critical goals and transformative approaches to create meaning, clarify purpose and challenge cultural assumptions or norms.

Long-term projects over several years with strong connections to external colleagues and organisations require a different type of team. Members of these teams may not recognise themselves as participating in teams, as activities are informal and self-organising, are often created by the commonality of learning, and are consolidated through social interactions. Examples include research collaboration between clinicians working with laboratory-based scientists and other experts, often from disparate geographical locations. The community of practice model first described by Wenger can be used to describe this type of group. [21] The driving characteristics of working collaborations are a shared knowledge or practice domain, a workplace-based context of learning and fluctuating levels of participation. Professional development activities combined with social interaction form an ongoing mechanism that supports inter-professional collaboration and the exchange of information.

It is useful to reflect on the numerous types of teams to which intensive care practitioners may belong to:

- select the most suitable model for the assigned goal
- measure the overall impact on patient outcomes, staff satisfaction or other outputs
- assess and prioritise workload, taking into account the combination of team-based activities occurring in the ICU.

Effective team-based practices are most commonly described in terms of organisational characteristics or leadership responsibilities; however, this fails to emphasise the benefits of participation to individual team members. These benefits, which are summarised in Box 5.3 , result in improved job satisfaction, staff retention, less sick leave, increased productivity and reduced costs.

Box 5.3

How team members benefit from team participation

Opportunity to be heard and for effort to be acknowledged
Psychological safety
Clarity of purpose, resulting in clear action plans, relevant tools and strategies
Mechanism to resolve conflict and address underperforming co-workers
More positive work environments
Support for professional development
Improved performance in time-critical stressful situations
Situational awareness

Specific Team-Based Interventions and Innovations

Broadly there are four categories of intervention that have been applied in critical care areas. These overlaps considerably depend on the programme methodology and content.

1. Leadership
2. Team building
3. Simulation and other forms of training
4. Organisational change.

Leaders are ‘visibly responsible and accountable for achieving the goals of an organisation’, and are the people on whom patients and colleagues depend to get things done. The style (autocratic vs. democratic) depends on the situation and may change as the situation demands (adaptive leadership). Leadership is the conglomeration of effective behaviours enabling the team to achieve its goal.

In summary, leaders refine and define the team goal; they create a vision and subsequently include the team in the design of the tools and mechanisms to achieve this vision. They do not avoid hard discussions and difficult decisions; they are honest about the effort and commitment necessary. They create an environment of psychological safety where team members feel secure and are willing to contribute within team hierarchies. Hierarchical discrimination is extremely variable and has a definite cultural association: where there is a high level of respect or fear of authority, individuals are extremely unlikely to either challenge or contribute, with clear implications for patient safety.

Explicit leadership behaviours, such as task assignment, directing co-workers and check-backs of vital signs are associated with fewer task failures and faster instigation of therapies, such as intubation and defibrillation in emergencies. Any group implementation of training or clinical practice improvement creates leadership obligations and opportunities. There is no widespread leadership training intervention applied in the intensive care setting, although several studies demonstrate improved outcomes associated with intensive care specialist-led care. [22] Courses in leadership, management and communication as part of post-graduate training programmes, such as those now mandated by the College of Intensive Care Medicine of Australia and New Zealand, proactively develop competencies for effective team participation and function.

For example when the impact of multidisciplinary teams on the 30-day mortality of over 100,000 intensive care patients was assessed, intensive care specialist care combined with multidisciplinary teams was associated with a 16% reduction in mortality, which was consistent across patient cohorts and greater severity of illness. [23] This benefit was similar between intensivist-led care or mandatory referral for consult and multidisciplinary care team input, but the greatest mortality reduction was seen when these were combined. The authors postulate that multidisciplinary rounds improve communication, enhance the implementation of agreed daily goals and encourage evidence-based care (e.g. pharmacist participation may reduce drug errors). Effective communication may also reduce the length of mechanical ventilation and ICU stay.

Training

A combination of team training, coaching and checklists to instigate communication in the operating room positively impacted surgical outcomes resulting in an 18% reduction in mortality at the hospitals that implemented the US Medical Team Training programme compared with a 7% reduction at the control hospitals [24] ; subsequently, implementation in over 187 sites in the United States resulted in the improved understanding of daily clinical goals following multidisciplinary rounds in the ICU and reduced lengths of ICU stay. [25]

TeamSTEPPS training is focused on improving patient safety by implementing an evidence-based teamwork system to improve communication and teamwork skills among healthcare professionals. [26] It has been used in paediatric, medical and surgical ICUs to train acute care teams, reducing times to placing patients on extracorporeal membrane oxygenation (ECMO) and decreasing nosocomial infection rates. [27] Other team-based initiatives have reduced rates of ventilator-associated pneumonia [28] and improved resuscitation time in trauma situations. [29]

Simulated scenarios can be used to explore, practice and refine the tools of communication, leadership, situational awareness and other team-based behaviours in a clinical context. Simulation may be high or low fidelity depending on the degree of accuracy with which the clinical scenario is replicated. Training may be stand-alone, specifically designed and maintained by full-time professional educators, or part of a clinical workplace. The important points are:

- participation requires an active choice to collaborate with colleagues
- simulation is an educational tool that has both strengths and limitations
- is suitable for common clinical situations in the intensive care setting

- may not require high-fidelity equipment; however, do require expert and experienced facilitators. [30]

Using case-based or simulation-based learning, there were significant improvements in leadership, team coordination, verbalising situational information in the intervention group and improved scores for clinical management. [31] Similar results were seen in the paediatric intensive care setting, where most found participation to be of benefit with a highly effective impact. The authors indicated that there is a 6- to 12-month learning curve in programme implementation, and repeated exposure is necessary to achieve meaningful benefits. [32]

Organisational Change

This is the final area of intervention. It includes teamwork, simulation and leadership training; however, the context in which the team model operates is an important element of the intervention and is formally assessed as part of the change process. [33] The integrated team effectiveness model illustrates how organisational contexts, such as processes, goals and structure, have a direct effect on team effectiveness. The breakthrough collaborative model uses organisational engagement and team alignment to a particular goal to achieve significant changes in clinical outcomes. [34] This has resulted in a significant increase in the rate of organ donation as measured by both donor identification and consent for donation. Teams use Plan-Do-Study-Act cycles to implement change in local practices supported by a senior clinical leader. Each team is provided with strategies and tools for change and participates in educational conferences, which allows more successful strategies to be shared and widely adopted. These educational opportunities foster team development and identify clinical leaders. Although effective in accelerating clinical change, these large-scale interventions are expensive and require widespread government, professional and organisational support (Box 5.4).

Box 5.4

How patients may benefit from team-based healthcare delivery

Improved continuity of care
Fewer adverse events
Shorter lengths of hospitalisation and mechanical ventilation
Better task delivery in emergencies
Decreased mortality
Lower costs of care so resources can be reallocated
Improved family outcomes through better communication

Further consolidation of team-based practice has occurred through partnering with patients and families in the co-design of clinical pathways and other aspects of service delivery, in response to national policy and regulatory settings. Similarly, collaboration with policymakers and funders in developing financially sustainable service delivery models also contributes to the habit of working in teams. Not all inter-professional interactions in the ICU conform to the idealised notion of teamwork. Alexanian and colleagues performed an ethnographic observational study in two large ICUs in North America and observed that most inter-professional interactions were more accurately described as collaboration, coordination or networking, and raised the issue of medical dominance of decision-making, which may relate to the particular legal responsibilities of physicians. [35] This study also suggests that *teamwork* is insufficient to describe the variety of ways health professionals interact in ICU and further testing of analytic frameworks such as those proposed by Boltey and colleagues [4] is required to capture the contextual factors that influence team interactions.

COVID-19 and Teamwork

The global pandemic has been a historic defining moment in the trajectory of critical care. There have been unprecedented challenges and effective teamwork has mattered more than ever, during and in the aftermath of the pandemic. It has been a case study on ICU team performance, demonstrating what teams can deliver despite unimaginable pressures. [36] The rapid and unanticipated onset of the pandemic was a catalyst for change, resulting in a permanent reframing of intensive care, our internal and external relationships, structures and priorities. As estates were re-purposed and care areas reorganised, teams who would not normally work closely were brought together from across organisations by necessity. Relationships between critical care areas were strengthened and people were unified by a shared objective.

Inevitably there were examples of destructive team behaviours and residual negative after effects, which will require proactive efforts to resolve. The ICU workforce was exposed to a prolonged period of uncertainty and fear. The immense physical and psychological stress experienced by ICU teams can be considered from several perspectives, each affecting the resilience of the immensely powerful but equally vulnerable workforce. As time went on, counter to the ‘heroes narrative’ there was a palpable sense of remorse as clinicians reflected on what had unfolded and whether they could have done things differently.

Box 5.5 summarises positive and negative impacts at a patient, individual clinician, team and organisational level.

Box 5.5

Impact of the COVID-19 on ICU

Virtual Meetings and Communication Platforms

- The inability to meet in person due to infection control restrictions during the pandemic led to an expansion in the use of virtual platforms for communication. The ability to ‘log in’ from home increased the availability and accessibility of the ICU workforce, allowing greater participation and a sense of belonging and enabling staff to be maximally informed.

- The flexibility of virtual meetings and educational events has permanently impacted the working patterns of ICU teams. This has allowed staff more autonomy in how they engage with non-clinical commitments, however, the ability to ‘attend’ from outside the hospital blurs the lines between work and personal life more than is healthy.
- There is a risk of colleagues not being completely ‘present’: simply being ‘logged in’ to a meeting does not translate to active participation and may contribute to dysfunctional group interactions.

Following the pandemic, we are a workforce with worldwide problems of training and retention and a high risk of burnout. [37] We need to collectively reflect, learn, adapt and recover to sustain our careers as ICU healthcare professionals. [38] There is a significant opportunity to advance team performance and resilience through research, to preserve patient safety and create a sustainable workforce, through the stages of a career in ICU.

As for all medical interventions, there are evidence-based recommendations for enhanced team performance, to ensure team sustainability and prepare for future challenges.

Salas and the team have highlighted evidence-based recommendations for optimising team performance and mitigating the performance risks from the main stressors of the COVID-19 pandemic. These have provided a useful framework to consider active steps that clinical leaders, managers and trainers can implement to enhance the future resilience of the ICU workforce by proactively monitoring and disrupting isolating behaviours that undermine confidence and well-being, consolidating psychological safety and acknowledging the effort and success of team members. [39]

More recently, clinicians and researchers interested in teamwork and patient safety have turned their attention to contemporary challenges of cognitive bias in clinical decision-making, workforce diversity, incivility, conflict resolution, distress and burnout. [40] Team-based practices improve communication, which has been demonstrated to reduce conflict and protect against burnout. Team diversity as described by gender, experience, cultural background, discipline and age is a marker of success for innovative thinking and avoids the cognitive trap of group thinking. Team stability is critical to effectiveness and has clear implications for the duration of clinical rotations, rostering practices and participation in emergency response and outreach teams. All these factors should be considered in the proactive process of team composition, particularly gender balance, which has a positive impact on team performance.

A detailed exploration of the optimal size of the ICU is beyond the scope of this chapter; however, it is important to make the distinction between a social group or network and the individuals/teams embedded in the group. There are cognitive limits to the number of interpersonal relationships that can be effectively sustained by individuals, which should influence the scale or size of organisational sub-structures. The optimal size of teams is intimately related to the nature/complexity of the tasks or activities undertaken (including learning), the stability of membership and the effectiveness of leadership.[41]

Summary

Team-based innovation in the specific context of high-acuity environments, such as the ICU, is increasing around the world (Fig. 5.7). There is a continuously growing evidence base that supports the following conclusions:

- Team-based interventions result in improved objective and subjective outcomes for patients, healthcare professionals and healthcare organisations.
- A broad range of well-developed tools, resources and programmes are available to support team-based practices.
- Significant expertise, experience, commitment and resources are necessary to achieve potential benefits.
- The innovation or intervention should be prepared or adapted for the specific context in which it is to be applied.
- Sustained performance improvement requires ongoing maintenance.

- Multidisciplinary teams of intensive care health professionals are valuable assets that provide considerable dividends to the organisations in which they work.
- Inter-professional collaboration in the clinical microsystem and teamwork within more focused teams occur simultaneously in the ICU and should be considered independently when designing interventions.

The composite diagram is divided into four main sections. On the left, a vertical arrow labelled hierarchy of engagement extends from a box labelled admission upward through the clinical microsystem to the community of practice. Adjacent to this path is a labelled section titled critical incident teams, containing six overlapping circles arranged around a central circle labelled intensive care. The surrounding circles are labelled cardiology, anaesthesia, trauma, paediatric, M E T, and hospital. In the centre, a large circular section is titled clinical microsystems. At its core is a smaller circle labelled patient, surrounded by role labels including cleaners, respiratory therapist, allied health, pharmacists, occupational therapist, physiotherapy, social worker, dietician, speech pathology, nursing, residents, and specialists. On the right, a radial cluster under the title context activity based teams features a central rectangle labelled intensive care connected to eight surrounding circles. These circles are labelled safety and quality, infection control, education, administration, clinical practice improvement, communication, research, and management. Beneath the central section is a horizontal arrow labelled continuity of patient care. It starts at admission and ends at come. Along this path are vertical markers labelled E D team, operating room, ward, and rehab. A rectangular section labelled patient journey contains two parallel segments titled resident doctors, each with three boxes labelled R N. Below this is a wider segment labelled specialist I C U, which includes a label for allied health. The entire diagram presents a multifaceted structure of integrated care surrounding the patient.

FIG. 5.7 Participation in teams that provide specific aspects of clinical care, support professional development and improve quality of care are important articulations of personal preference and autonomy. Such choices are likely to represent important opportunities to increase staff satisfaction and retention and to increase system capacity by matching skills and experience with personal interests. *ED* , Emergency department; *ICU* , intensive care unit; *MET* , medical emergency team; *RN* , registered nurse.

Pandemic and major incident planning

James O'Carroll and S. Ramani Moonesinghe

Types of Major Incident

There are several systems in which major incidents can be categorised. For example, the UK military uses the acronym CBRNE3T to categorise all potential hazards which could form a major incident. [2]

Chemical . This covers conventional chemical agent threats plus toxic industrial chemicals, riot control agents and chemical hazards derived from pharmaceuticals.

Biological . This covers live organisms, toxins and biological hazards deliberately employed to harm.

Radiological . This covers material or events that release ionising (alpha, beta, gamma radiation and neutrons) and non-ionising radiation (including directed energy).

Nuclear . This covers weapons or events that result in nuclear fission/fusion reactions.

Explosive (and ballistic) . This covers all consequences of explosive activity on human bodies including gunshot wounds, indirect fire, improvised explosive devices, shells and bombs.

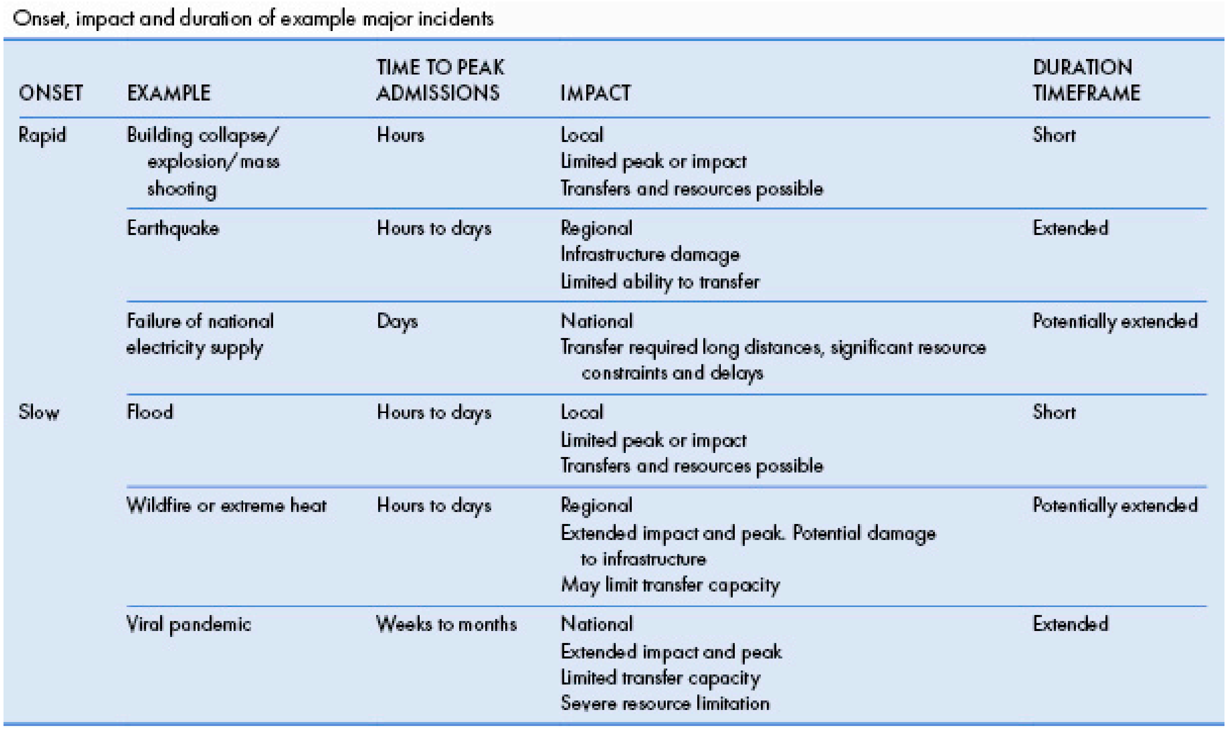
Environmental . This covers environmental conditions likely to cause harm such as heat, cold and altitude.

Endemic . This covers infectious diseases that pose a hazard to the health that are not deliberately released.

Trauma . This covers the trauma element of non-battle injury threats to health to complement the explosives (and ballistic) threats that also cause injury.

Critical care can be affected in many ways by a major incident. This is dependent on the onset, impact and duration of the incident (Table 6.1). The timeframe and peak will dictate the ability to use the available resources.

Table 6.1



Onset, impact and duration of example major incidents

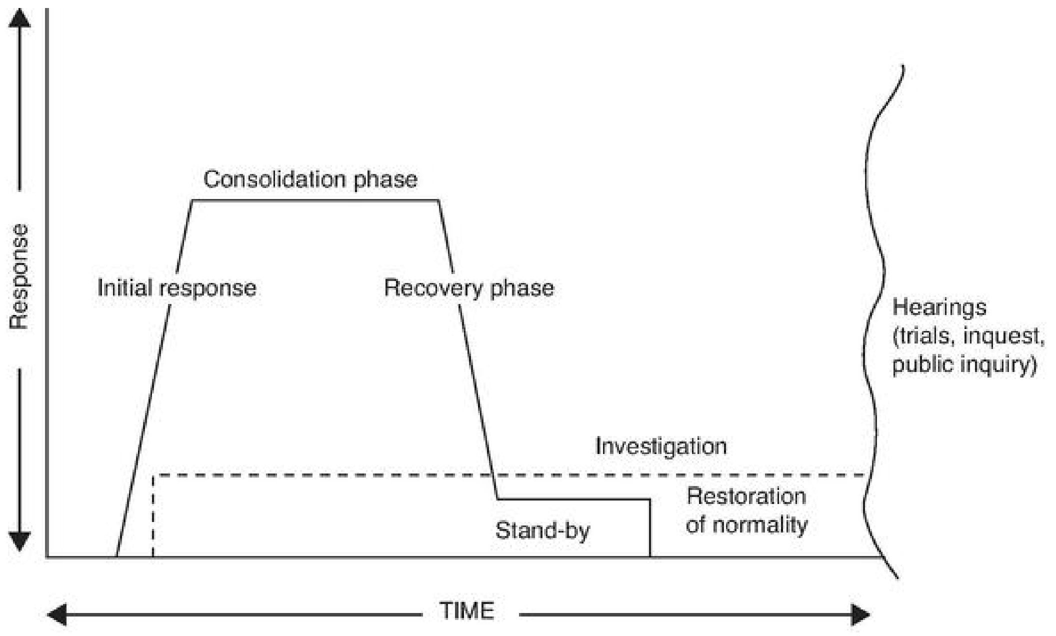
ONSET	EXAMPLE	TIME TO PEAK ADMISSIONS	IMPACT	DURATION TIMEFRAME
Rapid	Building collapse/ explosion/ mass shooting	Hours	Local Limited peak or impact Transfers and resources possible	Short
	Earthquake	Hours to days	Regional Infrastructure damage Limited ability to transfer	Extended
	Failure of national electricity supply	Days	National Transfer required long distances, significant resource constraints and delays	Potentially extended
Slow	Flood	Hours to days	Local Limited peak or impact Transfers and resources possible	Short
	Wildfire or extreme heat	Hours to days	Regional Extended impact and peak. Potential damage to infrastructure May limit transfer capacity	Potentially extended
	Viral pandemic	Weeks to months	National Extended impact and peak Limited transfer capacity Severe resource limitation	Extended

Major Incident Plans

Each institution is likely to have a standard major incident plan and it is important that staff who are expected to be part of a major incident have access to it, have read it and ideally participated in major incident simulation training. [3] Once most major incidents are declared, it is too late to read the document for the first time. It is recommended that each institution has a critical care expert on the planning committee to guide the response. It is not possible to have a specific plan for every type of major incident, therefore the plan should have a structure that can be adapted to different forms of mass casualty or major incidents, and critical care provision is key to this plan. In the United Kingdom, critical care networks connect services in different hospitals to each other and support the development of emergency plans that cover a specific geographical area. This supports the provision of specialist input and enables units to work together in the face of a major incident that could overwhelm individual local services. [4]

Most major incidents can be considered to have four stages (Fig. 6.1)

1. Initial response
2. Consolidation phase
3. Recovery phase
4. Restoration of normality



Response
Consolidation phase
Initial response
Recovery phase
Hearings
(trials, inquest,
public inquiry)
Investigation
Restoration
of normality
Stand-by
TIME

The graph shows the vertical axis labelled response and the horizontal axis labelled time. A stepped curve begins with a sharp upward slope labelled initial response, then levels off into a horizontal segment labelled consolidation phase. The curve then descends sharply into a segment labelled recovery phase. Below this curve, a dashed horizontal line begins just after the initial response and continues through the recovery phase, labelled investigation. Beneath this dashed line are two adjoining blocks labelled stand-by and restoration of normality. To the far right, extending vertically alongside the restoration of normality segment, is a bracket enclosing the label hearings that includes trials, inquest, and public inquiry. The structure presents a sequential flow from high-response emergency actions to investigative and restorative activities over time.

FIG. 6.1 Adapted from London Emergency Services Liaison Panel (LESLP). *Major Incident Principles* .

https://www.london.gov.uk/sites/default/files/leslp_mip_v11.5_dec_2021_-_public.pdf.5 .

Coordination of the Response

Internationally, various incident response systems have been developed to provide a framework for disaster response at national, regional and local levels, founded on a common set of principles. In the UK National Health Service (NHS), incident levels are graded between 1 and 4 (Table 6.2) and follows a change to a command-and-control structure as it increases. The United States and Australian models are based on a standardised emergency management system coordinating across multiple agencies in both the public and private sectors under each state or region's emergency plan. [5–8]

Table 6.2

Surge capacity

Surge capacity is the ability of a hospital or other healthcare system to expand beyond its normal operating capacity in the setting of an emergency. [9] The magnitude of the surge can be measured by the patient arrival rate per hour. [10] The nature and severity of the surge can be categorised by the type (e.g. trauma vs. infection vs. biohazard) and acuity (e.g. triage level) of the surge. Surge is a continuum from the ability to provide conventional to crisis care (Table 6.3).

Table 6.3

The surge continuum

RESPONSE CATEGORY	DESCRIPTION
Conventional care	The staff, stuff and space used are consistent with daily practices within the institution. These spaces and practices are used during a major mass casualty incident that triggers the activation of the facility's emergency operations plan.
Contingency care	The staff, stuff and space used are not consistent with daily practices but maintain or have minimal impact on usual patient care practices. These spaces or practices may be used temporarily during a major mass casualty incident or on a more sustained basis during a disaster or pandemic.
Crisis care	Adaptive staff, stuff and space are not consistent with usual standards of care but provide sufficient care in the setting of a catastrophic disaster or pandemic. Able to provide the care to patients given the circumstances and resources available.

Adapted from Hick JL, Einav S, Hanfling D, et al. Surge capacity principles: Care of the critically ill and injured during pandemics and disasters: CHEST consensus statement. *Chest* . 2014;146(4 Suppl):e1S-e16S. [11]

Depending on the role of the hospital in the community response (e.g. the only major trauma centre or paediatric critical care unit in the area) and the hazards identified in the area (e.g. risk for earthquake and flooding or terrorist attack), it may be prudent to plan for additional conventional capacity. Most major incidents can be managed using conventional and occasionally contingency care. In some thankfully rarer occurrences, a crisis situation may exist when resource(s) are in such shortage that decision-making moves from being patient-centred to population-centred, to maximise the use of available resources with the hope of saving more lives. This shift may necessitate resource triage. Mass casualty events involving more than 40 patients are rare, with modelling suggesting that 20% surge capacity is sufficient. [12] In 2003, the Joint Commission on Accreditation of Healthcare Organisations (JCAHO) described the factors involved in surge capacity as, '…encompasses potential patient beds; available space in which patients may be triaged, managed, vaccinated, decontaminated, or simply located; available personnel of all types; necessary medications, supplies and equipment and even the legal capacity to deliver health care under situations which exceed authorised capacity.' [13] This has later been described as the 4 S's of surge capacity 'staff, stuff and space and systems'. The ability to have additional capacity in these events relates to the provision of these four key resources. [14–17]

- **Staff:** the availability of appropriately trained healthcare professionals for the critical care environment.
- **Stuff:** the medical equipment, supplies and drugs required for patients in critical care.
- **Space:** the physical space within and, in extremis, outside of the hospital to provide critical care.
- **System:** the planning and leadership to operationalise and optimise the response effort.

The lack of any one of these will reduce the ability of the system to provide effective increased capacity. It is therefore important to understand and plan for each one of these potential constraints.

Mutual aid is the gift, loan, or exchange of resources for mutual current or future benefit. Irrespective of the cause of the major incident, it is unlikely that all hospitals will be at the same level of surge at the same time, with some having more capacity or provision for care or available resources. In this case, mutual aid can be used to alleviate some of this strain. Many hospitals run at near capacity across all services, especially those such as critical care, operating theatres and acute admission areas.

Creating admission space poses a difficulty, especially in an urgent setting. In the event of a major incident, it is essential for there to be available resources and space. To facilitate this, this includes but is not limited to, expediting the discharge of ward patients, stepping down those who are suitable from higher to lower levels of care and the cancellation of scheduled surgery other than urgent procedures and transplant surgery.

Staff

The most significant challenge in maintaining safe, effective care for those who are critically ill in a major incident is the availability of a sufficient and suitably trained workforce. As well as the usual challenges in many institutions around workforce recruitment, retention and day-to-day staffing, in the case of natural disasters or communicable disease outbreaks, the hospital staff may be casualties, infectious, or required to isolate, further reducing the pool of available staff to the health system. A surge in admissions will exacerbate all these challenges, leaving staff stretched, and themselves at risk of physical and psychological harm.

It is recommended that staff carry their hospital identification when they may be called upon in a major incident, to allow them access to the hospital. A mechanism should be in place where staff are able to be contacted and called to assist if able in the event of a major incident. However, it is important to ensure there are sufficient staff available for subsequent and ongoing shifts.

During higher levels of surge conditions, usual staff-to-patient ratios of critical care health professionals may not be achievable. This may necessitate delegation of tasks not specific to critical care. Healthcare staff who do not normally work in a critical care environment can be upskilled or cross-trained. Nursing skills which are not unique to critical care such as observations, personal care, urinary catheterisation and medication delivery amongst others can be allocated to non-critical care nurses. Operating room and recovery/post-anaesthetic-care unit staff can be called upon to provide additional nursing and therapist support. Pharmacy services can provide additional support on medication management and preparation of infusions. Critical care physicians can supervise those from other specialities. In addition, skills which are not unique to critical care can be delegated beyond this; for example anaesthesia to supervise transfers, interventional radiology for central venous or arterial catheterisation, or renal physicians and nurses to supervise renal replacement therapy. Prior to them being needed, plans should be made and confirmed with all specialties regarding the supervision, planned numbers and specific roles necessary. As an aspiration, training should be available before the requirement.

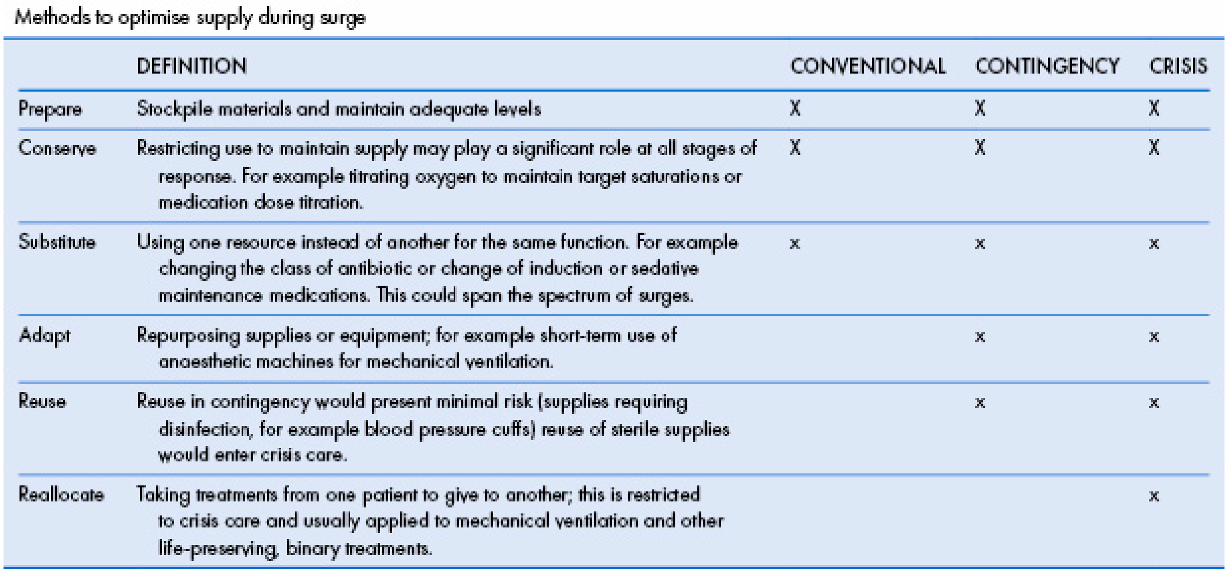
Surge plans should consider the source of staff who would provide additional support to critical care services, and the thresholds for activating support staff (which would usually necessarily require other services to stop or reduce). In addition, preparatory arrangements should be made, such as maintenance training in critical care basics for potential surge staff, and human resources permissions, to ensure that there are no barriers to rapid activation of support.

Stuff

Those admitted to critical care environments will have specific needs related to monitoring, requirements for inventions with specialist equipment and/or medications. This need can provide challenges in major incidents. In many incidents, the ability to provide invasive mechanical ventilation is the limiting factor. Each hospital site should know the total number of adult and paediatric patients they are able to provide invasive or non-invasive ventilation and the higher levels of care available. In addition, each hospital site should work with its estate team to ensure that the infrastructure can support the surge in patients in terms of the electrical supply to each bed space and, importantly, the supply of piped gases, particularly oxygen. Consideration must be made of how to maintain adequate oxygen supply to hospitals; in the case of a pandemic surge, negotiation at the governmental level with suppliers may be necessary. Even if oxygen supply to hospitals can be maintained, many institutions particularly with older estates, have higher maximum oxygen flow supplies in the operating and emergency departments and critical care units, than everywhere else in the hospital. This means that when normal wards are converted to provide critical care, the oxygen flow demand can exceed the maximum flow potential, with risks of oxygen flow failure and unpredictable differential flows to different patients. This is particularly a risk when providing high-flow oxygen via face masks, continuous positive airway pressure devices and high-flow nasal oxygen devices. Careful planning of which wards might be converted to provide critical care in the event of a surge in patients is therefore required, considering these issues.

An acute and prolonged surge in patients will additionally strain consumable resources available at local, regional, national and, occasionally, international levels. The CHEST guidelines have outlined methods to optimise supplies during conventional, contingency and crisis surges based on preserve, conserve, substitute, adapt, reuse and reallocate [14] (Table 6.4). Regional and national procedures may constrain and ration consumables which are in short supply. In addition, it is prudent that sufficient supplies of personal protective equipment are available to safeguard staff against exposure to pathogens and potential hazards from the incident.

Table 6.4



Methods to optimise supply during surge

	DEFINITION	CONVENTIONAL	CONTINGENCY	CRISIS
Prepare	Stockpile materials and maintain adequate levels	X	X	X
Conserve	Restricting use to maintain supply may play a significant role at all stages of response. For example titrating oxygen to maintain target saturations or medication dose titration.	X	X	X
Substitute	Using one resource instead of another for the same function. For example changing the class of antibiotic or change of induction or sedative maintenance medications. This could span the spectrum of surges.	x	x	x
Adapt	Repurposing supplies or equipment; for example short-term use of anaesthetic machines for mechanical ventilation.		x	x
Reuse	Reuse in contingency would present minimal risk (supplies requiring disinfection, for example blood pressure cuffs) reuse of sterile supplies would enter crisis care.		x	x
Reallocate	Taking treatments from one patient to give to another; this is restricted to crisis care and usually applied to mechanical ventilation and other life-preserving, binary treatments.			x

Medicines shortages can be commonplace during major incidents. Few countries manufacture all the drugs their population requires, and most are reliant on supply chains which are prone to disruptions, especially if transportation is impaired. Further, with international incidents, such as infectious pandemics, overall demand can outstrip supply. It is prudent therefore for reasonable stockpiles of essential supplies to be maintained, to provide an adequate inventory of critical supplies to meet some surge demands. Hospitals and critical care networks should aim to establish sufficient supply chains, engage in strategic stockpiling and use inventory management systems to guide their usage. The logistics of maintaining a stockpile should not be underestimated, including storage facilities and the maintenance of ‘in-date’ products, with items due to expire being prioritised for use in the system. Such logistics require coordination across national, regional, sector or consortium levels; this may make it a difficult challenge to overcome in any health system, but in particular, one which is not federated, such as the UK’s NHS.

Space

The critical care environment is a level of care that is not defined by a physical location. During the surge of admissions following a major incident, it may be necessary to provide critical care in other areas of the hospital. It is important that these locations are fit for purpose in terms of physical space, infrastructure including electricity and piped gas supply at sufficient pipeline pressures. In extremis, there may be the necessity for ‘field hospital type’ critical care areas, however, this should be only once all else is utilised. Additional capacity can be increased by the cessation of scheduled elective work, mutual aid and the use of intrahospital transfers. It must be noted that the use of intrahospital transfers, whilst facilitating the safe transfer of patients, reduces the staff available and may best be facilitated by dedicated transfer teams with limited additional clinical responsibilities.

System

During normal times, critical care units and hospitals have complex systems that command triage and patient flow to meet the dynamic demand. During an acute surge event, usually, an incident commander will oversee these systems. This incident command system is used to assess the demands on resources posed and, with clinical and operational leadership input, provide targeted recommendations. These recommendations can be used to conserve or allocate resources for the response. The incident command should communicate frequently with other local critical care units and hospitals, in addition to regional or national authorities, to allow real-time tracking of the events. Systems are strengthened by a firm understanding of current resources, frequent data tracking with early warnings of a surge and strong pre-existing lines of communication across networks and to national bodies.

Communication

Clear communication is essential. In a major incident, traditional methods of communication of mobile, landline telephones and pagers may become overwhelmed either from overloaded networks of the provider or as the hospital switchboard has increased volume of outside calls due to people attempting to gather information, for example relatives of casualties, or the media. Many institutions may utilise handheld radios for key team members to communicate during the initial phase. It is prudent to have thorough documentation perhaps aided by the use of a dictaphone.

Information and Data Sharing

Sharing information in the initial phase of a major incident is critical to ensuring the appropriate resources are put in place. In the United Kingdom, the Joint Emergency Services Interoperability Principles (JESIP) identifies METHANE as the preferred model to share information to promote a shared situational awareness. [18]

- **Major incident declared?**
- **Exact location**
- **Type of incident**
- **Hazards present or suspected**
- **Access – routes that are safe to use**
- **Number, type, severity of casualties**
- **Emergency services present and those required**

In most cases, this will be highlighted by ambulance services. However, in a major incident from an infectious disease outbreak, this can come from the public health or local government departments. During a major incident, the response can be enhanced with the effective distribution of information about patients, events and/or epidemiology. This data should be shared on a regular basis; this is particularly pertinent for infectious disease outbreaks where information and robust data collection can provide a better understanding of the disease process, facilitate critical care capacity, resource utilisation and the reporting of patient outcomes. Real-time data-sharing platforms can aid situational awareness, enable predictive modelling and guide resource allocation decisions.

CRITCON and Other Reporting Tools

CRITCON was designed as a simple method to collect, report and interpret local and regional critical care capacity as a response to winter flu and is a recognised method to describe the operational and resource constraints in the event of a surge in patients. A modification was proposed and adopted during the COVID-19 pandemic by the Intensive Care Society, [19] with the overarching aim being to ensure that the 'hotspots' are visible regionally and nationally.

CRITCON-PANDEMIC has 5 levels 0 to 4, corresponding to '0 – normal', '1 – preparatory', '2 – sustained surge', '3 – super surge', and '4 – code red' which enables individual critical care units under unusual stress to trigger mutual aid, facilitating shared decisions such as transfers and postponement of scheduled surgery. This is likely to have further future iterations and is specific to critical care.

Planning for Unique Populations

A major incident may require the hospital to care for and stabilise a population which they do not normally treat, for example, trauma, burns and/or paediatric populations. The hospital must have planned access to the necessary equipment needed. In addition, ensuring that the staff members have the training, some quick-reference resources available to care for these patients and an ability to have a contact for advice and consultation of care from a centre which has that expertise. [20]

Ethics of resource allocation

Difficult decisions are made by critical care teams on a daily basis, for example cancellation of surgery, transfer between institutions and early discharge when capacity is constrained. Major incidents, particularly if sustained, such as during infectious epidemics, will augment these challenges, both in terms of the number of decisions to be made and the magnitude of their consequences. Principles of care provision will therefore inevitably move further along the continuum of patient-centred to utilitarian care. This leads to significant moral and ethical challenges for clinicians.

The availability of the key resources will determine the quality and impact of a response to a major incident. Of these, space may be the most easily managed – operating departments may be converted to critical care units, field hospitals may be rapidly established. Provision of 'stuff' and staff may be much more challenging, particularly in the event of a communicable disease epidemic which affects whole health systems. In critical care, the availability of hardware (ventilators, monitors, syringe drivers, to name a few) and consumable items, may be a key determinant of the quality of care which can be offered. However, some degree of critical care support is likely to be possible, even if of substantially lower quality than would normally be available. Dozens of ethical principles can be applied to resource allocation during times of surge, importantly keeping social justice at the core. Many have advocated for the development of an ethical framework which can guide decision-making in these circumstances. Each major incident or pandemic is likely to create different ethical challenges, including those related not just to the patients directly affected by the incident, but those potentially indirectly impacted (e.g. patients who have surgery cancelled or care delayed), development of a set of principles which can be adapted to the specifics of the situation in hand may be the most useful future research development.

Debrief and Moral Injury

Following a major incident, there may be a protracted, public and politicised inquiry. The process may take many months to years and the lessons learnt from the event should be disseminated throughout the healthcare community to improve the responses when other major incidents inevitably occur. Prior to this, it is important that staff are given the ability to debrief. During and following the incident, all staff should be encouraged to participate in debriefing exercises and be offered counselling and support as required.

The psychological wellbeing of all those involved in the response and aftermath of a major incident is paramount. Those working in critical care, who will have been with the most unwell patients, and may have witnessed the highest number of deaths, are at particular risk – and there may be a knock-on impact on their families and friends. The term moral injury originates from the military and can be defined as the psychological distress that results from actions, or the lack of them, which violate someone's moral or ethical code. [21] Moral injury is not a mental illness unlike post-traumatic stress disorder or depression, however, those who develop moral injury are likely to experience negative thoughts about themselves or others as well as intense feelings of shame, guilt or disgust. [22] Despite staff acknowledging that the psychological impact of experiencing a major incident at work could be considerable, few reported any degree of psychological preparedness. Several potential mechanisms can help mitigate the negative moral effects of the traumatic situation, with evidence to suggest that psychosocial training in the workplace could be beneficial for mental health and encourage supportive workplace interactions. It is therefore important that prior to such events these mechanisms are in place; this could be done through the provision of training and workshops incorporating mental health education to reduce stigma and improve workplace connections. [23]

Conclusion

Pandemics and major incidents will both continue to be a risk and an unfortunate inevitability in society. Critical care can represent the first point of contact and a final bastion for the management of many of those affected.

It is therefore of paramount importance that there are plans and mitigations in place. Measures are required to have sufficient structure to be effective while maintaining flexibility to support the individual dynamics and characteristics of the incident.

Transport of critically ill patients

Roy Fischer and Krista Mos

Introduction

Critical illness and injury are not necessarily defined by patient location. In addition, patients may overwhelm the level of care available at their current location or require specific investigations or treatments not immediately available to them. For this reason, the transport of critically ill and injured patients occurs frequently.

Critical care patient transport has traditionally been divided into two groups: patient movement within a hospital (intrahospital) or movement between hospitals (interhospital or interfacility). In addition, a select group of critically ill or injured patients not located in a hospital facility may be managed by physician-led medical team prior to retrieval to a hospital. Therefore a third division (primary response or pre-hospital care) is well recognised.

The internationally widespread deployment of medical teams for critically ill patient management and retrieval from both healthcare facilities and pre-hospital locations has resulted in the recognition of pre-hospital and retrieval medicine as a distinct subspecialty. [1]

Intrahospital Transport

The safest place for the critically ill patient is in the intensive care unit (ICU) connected to a modern ventilator and physiological monitoring, a nurse present to care for the patient and rapid access to nursing and medical assistance. Transports are usually required to facilitate critical investigations and interventions or to move the patient from one critical care area to another. Critically ill or injured patients with limited or no physiological reserve undergoing such transports are at risk of clinical deterioration and adverse events are well reported.[2,3] To reduce the mortality and morbidity associated with patient movement, a structured approach utilising high-level clinical personnel who have the correct equipment, training and sufficient planning time is required.

Moving the patient should be associated with little or no compromise in their condition. Unfortunately, this is not the case, with complication rates as high as 70% reported. A recent systematic review and meta-analysis showed a pooled adverse event frequency of 26.2% with a 1.47% frequency of life-threatening adverse events.[4] There was marked heterogeneity between the studies which may be due to differences in reporting, equipment, training or patients. One-third of these events are equipment related.[5] Deterioration in gas exchange[6] and increased rates of ventilator-associated pneumonia are common.[7] However, management is changed in 40%–50% of patients, thus justifying the risk.

Patients with unstable physiology should not be transported for non-urgent interventions or investigations. However, where the intervention or investigation is deemed critical to achieving patient stability or providing definitive management, the benefits in patient outcomes will outweigh the inherent risks of transport. Therefore the transport can be seen as part of the patient's therapeutic requirement and stabilisation process. On occasions when the patient's need is so acute, or the likelihood of irreversible deterioration in transit is so high, consideration should be given to facilitating such interventions or investigations in the ICU rather than the location where these procedures would normally occur.

When preparing for intrahospital transport, the following structured approach is recommended:

- Prior planning to ensure minimal manual handling and to minimise the time away from the ICU.
- Clinical reassessment should occur swiftly, systematically and, whenever possible, with the patient already supported on the equipment that will be used during transport.

- The airway should be checked and secured, endotracheal suction performed, ventilation and oxygenation optimised, adequate and patent vascular access secured and drainage devices measured and emptied.
- Sedation and analgesic requirements should be addressed and any drugs required for transport (including additional infused agents) pre-drawn and labelled for immediate use.
- Ensuring that the patient's clinical record remains with the team caring for the patient.

Computed Tomography and Magnetic Resonance Imaging Scanning

Computed tomography (CT) scanning is the most common ICU diagnostic intervention requiring patient movement. Patients with head injuries and those without a secure airway at risk of aspiration or respiratory decompensation require extra attention. When the CT scan is booked it is vital to liaise with the radiologist and other treating teams involved to ensure that the scan will address all the clinical questions. It is important to secure adequate vascular access for the pressure injection of intravenous (IV) contrast prior to leaving ICU; standard multilumen central lines are not suitable. Specific peripherally inserted central catheter (PICC) or central venous catheter (CVC) lines that are suitable for pressure injection may be used or a secure large bore peripheral IV inserted.

Repeated CT scanning of head-injured patients is common. In these patients with decreased cerebral compliance, movement or changes in body position or partial pressure carbon dioxide ($PaCO_2$) can result in significant elevations in intracranial pressure (ICP). Although movement-induced changes in ICP can be reduced with sedation, very little can be done about body position. Changes in $PaCO_2$ are usually due to variations between ICU and transport ventilators. Technological improvements mean that modern transport ventilators can deliver ventilation much more accurately than older devices. However, differences in circuit design, calibration and end-tidal CO_2 ($ETCO_2$) sampling mean that it remains good practice, if time permits, to establish the patient on the transport monitor and ventilator 10–15 minutes prior to departure. This allows time to take an arterial blood gas sample to establish the relationship between $PaCO_2$ and $ETCO_2$ and define what $ETCO_2$ should be targeted.

Radiation exposure for both the patient and staff needs to be considered. A stable patient who is adequately monitored with alarms activated can be observed by staff outside the room. The patient should be moved back to the ICU as soon as scanning is completed.

Magnetic resonance imaging (MRI) is increasingly used as a diagnostic and prognostic tool for a wide range of ICU patients. MRI scanning entails greater risk than CT due to the unique environment, longer duration of scans and greater need for patient immobility (potentially necessitating sedation in non-intubated patients). The major problems with MRI are the effect that the magnetic field may have on ventilators, monitors and infusion pumps, and the potential for these items to become effective missiles by being attracted to the magnet. Recently, there has been the development of monitoring and ventilators that are MRI compatible and the acceptance of standards for equipment in the MRI. These magnetic resonance standards are: MRI safe, conditional or unsafe. Safe and unsafe are self-explanatory, whilst conditional relates to equipment that is safe when used under certain pre-determined conditions, for example distance from the magnet. Whilst larger ICUs increasingly have MRI-compatible transport equipment, this is not the case at every facility. More often facilities have MRI-safe anaesthesia machines for the provision of general anaesthesia during the MRI examination. This equipment is ‘foreign’ to most ICU staff and often is not used owing to lack of familiarity. The third option is to use non-MRI–compatible equipment but to keep it outside of the scan room; ventilator and infusion lines can be lengthened with long extensions and routed through openings in the wall. This then only requires a dedicated MRI monitor inside the scan room. Not all ICU patients may be suitable to undergo MRI scanning. The magnetic field of the MRI scanner may pull on some metal-containing implants or cause heating due to the radiofrequency energy; in addition, the magnetic field can cause malfunction of implanted devices (e.g. pacemakers). Prior discussion with the MRI unit must occur before the patient is moved from the ICU; this is important to ensure patient safety and to avoid denying patients the potential diagnostic benefit of MRI unnecessarily. With improving technology, some types of devices that were previously an absolute contraindication to MRI may now be suitable under some circumstances. Most MRI units will require an MRI checklist to be completed prior to scanning.

It is important to note that the magnetic field is always active and staff entering the scan room need to be screened for metallic devices either implanted or on their person that may be dangerous.

Operating Theatre and Interventional Radiology

Transfer to and from the operating room should be done by the anaesthetist who will be caring for the patient during the procedure. This allows handover in the controlled environment of the ICU and minimises the number of people entering the sterile operating room environment. For complex interventional radiology procedures, the same arrangement should occur. For diagnostic or simpler interventional procedures the ICU team undertakes the transfer and care during the procedure. It is vital that the team has an understanding of the procedural requirements including patient positioning, the need for analgesia, the possible complications and the specific treatments/physiological targets required.

Staffing

A dedicated team of two clinical staff, free from other duties, should be used. Both team members should be thoroughly familiar with the transport process, equipment and environment. Traditionally this team is made up of a credentialed ICU medical officer and a nurse. In some centres, the medical officer may be replaced by another appropriately trained transfer-competent healthcare professional. The team should possess the requisite skills and knowledge to independently manage critically ill patients in transit and to deal with anticipated emergencies. The more complex and unstable the patient is, the more experienced the team must be. For very unstable patients an additional nurse and more senior doctors may be required. Assistance with safe patient, trolley and equipment movement is also needed. Therefore non-clinical hospital support staff are part of the team and should be included in all briefs and contingency planning.

Equipment

Transport equipment should be regularly checked and serviceable. Powered devices should be fully charged, with power cords accessible to facilitate the use of mains power in the event of delay. Where possible, equipment should be lightweight, robust and standardised throughout the ICU and hospital. In transit, equipment should be secured (not resting on the patient) but readily accessible. Dedicated transport bridges or gantries are commonly used. Dedicated transport packs or boxes ensure safe carriage of consumable items, resuscitation equipment and drugs. Equipment required for emergency airway management (e.g. bag valve mask, laryngoscope, airway devices and endotracheal tubes), oxygen and suction must be immediately available.

Monitoring

As a minimum, intubated and ventilated patients requiring intrahospital transport should have the following monitoring instituted [8]:

- Continuous ETCO_2
- Continuous SpO_2
- Continuous invasive or intermittent noninvasive blood pressure (BP)
- Continuous three-lead electrocardiography (ECG).

Ideally, a cardiac monitoring device should also provide cardiac defibrillation and external cardiac-pacing capability. Patients requiring transport with more advanced monitoring in situ should be considered on a case-by-case basis. For example ongoing ICP monitoring is critical to ensure the avoidance of profound unmonitored falls in cerebral perfusion pressure in an ICU patient with a severe head injury, whereas pulmonary artery pressure monitoring may be excluded from the transport requirements in the haemodynamically stable patient. External ventricular drains (EVD) require special attention as it is imperative that the device is levelled accurately. Generally, they are clamped for significant changes in patient posture and reopened as soon as possible but only once an accurate level can be re-established. For CT this often means transferring the patient's head up with the levelled EVD attached to the bed and only clamping the EVD immediately before the patient is laid flat to slide onto the CT table. Underwater seal thoracic drains also have specific requirements, they should not be clamped and must be kept below the patient level during transport.

Interhospital Transport

With rising expectations for high-level care by the community in both metropolitan and rural locations and with the care for critically ill and injured patients becoming increasingly centralised in large, tertiary, metropolitan ICUs, the need to transfer patients between healthcare facilities has also increased. Such a demand has seen the development of dedicated specialist retrieval teams. Historical models of interhospital patient transfer utilising junior medical staff as 'patient escorts' have much higher rates of hypotension, acidosis and death. [9] Thankfully this type of transport has become increasingly rare with the introduction of specialist retrieval services.

The general principles of patient transport regarding equipment, patient monitoring and clinical requirements remain the same irrespective of the physical location of the patient. Standards for transportation of the critically ill have been widely promulgated and must be followed whether it is a complex unstable patient being moved long distances or a semi-elective CT scan in a stable ICU patient. [8], [10]

Retrieval Clinical Coordination and Advice

Retrieval clinical coordination describes the process whereby specialist medical, nursing, paramedic and ambulance service staff are involved in direct supervision of the primary and interhospital transport or retrieval of patients. This is to ensure:

- the safe and efficient use of expensive transport and retrieval services
- that high-level clinical advice is available prior to and during transport
- the patient is delivered in a timely manner to the most appropriate receiving hospital.

Not all patients who are referred for retrieval will require transport. Of those who do, not all will require a retrieval team. To ensure that this is addressed, an integrated systems approach is required. In general, a retrieval service will be used when the complexity of the patient exceeds the ambulance service's ability to transport the patient. Telemedicine is playing an important and increasing role in this process, not only in assisting decision making regarding retrieval activities (resulting in potential cost savings) but also in supporting remote and regional medical practitioners faced with acutely ill or injured patients, and in supporting a retrieval team before and during patient transport. For this reason, many retrieval coordination centres are co-located with ambulance service communication centres. In this way, clinical and logistic expertise is integrated. Knowing where key assets (transport platforms, such as road ambulances, helicopters and fixed-wing aircraft) and retrieval teams are at any time is crucial to effective retrieval clinical coordination. Real-time asset tracking or mapping systems and advanced radio or phone communication networks assist in this regard.

Retrieval Team Staffing

The aim of the team is at least to maintain, but ideally to increase the level of care during transport. This requires a team of sufficient size and skill to provide the full complement of care for the majority of patients being transported.

The minimum team should comprise two people; occasionally a very-low-acuity stable patient may be escorted by a single person. If multiple patients are to be transported, a recommended staffing level is $n+1$ where n equals the number of patients.[11]

Who makes up the team continues to be debated. In most cases, a doctor will be one member whilst the other can be a person with either an acute care nursing or an ambulance background. Other requirements include the ability to work and communicate as a team, a reasonable level of fitness and having no visual or auditory impairment or susceptibility to motion sickness. In aviation transport, the weight of the teams and their equipment is important as there is a maximum weight available. High team weights can limit the amount of fuel able to be carried, which may compromise some missions.

There may be some highly complex cases that will be outside of the team's capability, and supplementation of the retrieval team by additional specialist personnel may be required. For example an obstetrician or neurosurgeon[12] may be added depending on the type of mission. It is mandatory that the specialist is added to a standard team because of the latter's familiarity with working in the retrieval environment.

Training

Training should cover the following:

- Standard operating procedures for the service
- The use of scenarios to teach common procedures and principles
- Familiarity with the various transport platforms to be used; this would include safety briefings on aerial assets and may include helicopter underwater escape training (HUET) and crew (cockpit) resource management (CRM)
- Communication procedures
- Understanding of the effects of altitude and flight on patient (and team) physiology.

Equipment

General Considerations

Minimum equipment standards for supplies, equipment and monitoring have been published.[8,10] The equipment carried is often a compromise between providing for every conceivable situation and being lightweight and mobile. In some cases, it is appropriate to have additional specialist packs that are taken only when warranted by the clinical situation; for example a Sengstaken–Blakemore tube or temporary transvenous pacing wire is taken only when a gastrointestinal (GI) haemorrhage occurs in a patient who might have varices or the patient has symptomatic complete heart block. This requires good communication and a robust coordination process.

A suggested list of equipment is given in Box 7.1 . Exact requirements will vary from service to service based on the anticipated mission profiles.

Box 7.1

Suggested equipment schedule for interhospital critical care transport

Respiratory equipment

Intubation kit:
  – Intubation/RSI checklist
  – Endotracheal tubes and connectors
  – Introducers, bougies, Magill forceps
  – Video laryngoscope (preferable) or laryngoscopes with appropriate blades and redundancy
  – Ancillaries: cuff syringe and manometer, ‘gooseneck’ tubing, HME/filter(s), securing ties, lubricant
Alternative airways:
  – Simple: Guedel and nasopharyngeal
  – Supraglottic: second generation
  – Infraglottic: surgical cricothyrotomy kit and tubes
Oxygen masks (including high Fi_{O2} type), tubing, nebulisers
Suction equipment:
  – Main suction system – usually vehicle mounted

– Spare (portable) suction – hand-, O_2-, or battery powered
– Suction tubing, Yankauer, catheters and spare reservoir
Self-inflating hand ventilator, with masks and positive end expiratory pressure (PEEP) valve
Portable ventilator with disconnect and overpressure alarms, oxygen failure alarm
Ventilator circuit and spares
Waveform capnography
Pleural drainage equipment:
– Inter-costal catheters and cannulae
– Surgical insertion kit and sutures (see below)
– Heimlich-type valves and drainage bags
Main oxygen system (usually vehicle mounted) of adequate capacity with flowmeters and standard wall outlets
Portable/reserve oxygen system with flowmeter and high pressure outlet

Circulatory equipment

Monitor/defibrillator/external pacemaker, with leads, electrodes and pads
IV fluid administration equipment:
– Range of fluids: isotonic crystalloid, dextrose
– High-flow and metered flow-giving sets
– IV cannulae in a range of sizes: peripheral and central/long lines
– IV extension sets, three-way taps and needle-free injection system
– Syringes, needles and drawing-up cannulae
– Skin preparation wipes, IV dressings
– Pressure infusion bags (for arterial line also)
– Alternate vascular access equipment (e.g. intra-osseous [IO])
BP monitoring equipment:
– Arterial cannulae with arterial tubing and transducers
– Invasive and noninvasive (automated) BP monitors

– Aneroid (nonmercury) sphygmomanometer and range of cuffs (preferably also compatible with NIBP)
Pulse oximeter, with finger and multisite probes
Syringe/infusion pumps (minimum two) and appropriate tubing

Miscellaneous equipment

Urinary catheters and drainage/measurement bag
Gastric tubes and drainage bag
Minor surgical kit (for inter-costal catheters (ICC), CVC lines, cricothyrotomy, etc.):
  – Sterile instruments: scalpels, scissors, forceps, needle holders
  – Suture material and needles
  – Antiseptics, skin preparation packs and dressings
  – Sterile gloves (various sizes); drapes ± gowns
  – Basic thoracotomy equipment
Cervical collars, spinal immobilisation kit (e.g. Vacmat), pelvic binder, splints
Thermometer (nonmercury) and/or temperature probe for the monitor
Warming equipment (e.g. reflective blanket, chemical blanket or fluid warmer)
Bandages, tapes, heavy-duty scissors (shears)
Personal protective equipment (PPE): gloves, gowns and eye protection (may need extra for pre-hospital response or aircraft, e.g. helmets, flame retardant flight suit and life vests)
Sharps and contaminated waste receptacles
Pen and folder for paperwork
Torch ± headlight
Drug/additive labels and marker pen

Pharmacological agents

CNS drugs:
  – Narcotic and nonnarcotic analgesics
  – Anxiolytics/sedatives

- Antipsychotics
- Anticonvulsants
- IV anaesthetic induction agents
- Antiemetics
- Local anaesthetics

Cardiovascular drugs:

- Antiarrhythmics
- Anticholinergics
- Inotropes/vasoconstrictors
- Nitrates
- Beta blockers
- Other hypotensives

Electrolytes and renal agents:

- Sodium bicarbonate
- Calcium (chloride)
- Magnesium
- Potassium
- Loop diuretics

Endocrine and metabolic agents:

- Glucose (concentrate) ± glucagon
- Insulin
- Steroids

Other agents:

- Neuromuscular blockers: depolarising and nondepolarising
- Narcotic and benzodiazepine antagonists
- Bronchodilators
- Proton pump inhibitors
- Anticoagulants

    - Thrombolytics
    - Vitamin K
    - Antibiotics ± antivirals
    - Oxytocics
    - Tocolytics
    - Diluents (saline and sterile water)
    - Treatment for elevated ICP (e.g. hypertonic saline or mannitol)

Additional/optional equipment

- Portable ultrasound machine
- Transvenous temporary pacing kit and pacemaker
- Blood (usually O negative) and/or blood products
- Additional infusion pumps and associated IV sets
- Obstetrics kit with neonatal equipment
- Additional paediatric equipment (depending on the capability of the basic kit)
- Antivenin (polyvalent or specific)
- Specific drugs or antagonists

BP , Blood pressure; *CNS* , central nervous system; *CV* , central venous; *FONA,* front of neck access; *HME* , heat moisture exchangers; *ICC* , inter-costal catheters; *ICP* , intracranial pressure; *IO* , intra-osseous; *IV* , intravenous; *NIBP* , noninvasive blood pressure; *PEEP* , positive end expiratory pressure; *RSI,* Rapid sequence induction.

Transport monitors, infusion pumps and ventilators must work out of the transport vehicle. They must be battery powered whilst ideally allowing for the utilisation of ambulance or aircraft power during transport. Batteries in most modern systems are lithium. Battery life is quoted for new batteries and with time this value decreases. Planning on a battery life of 50% of that quoted is prudent. Spare batteries can be carried, subject to any aviation restrictions, but changing them may result in a temporary interruption of function.

During transport the equipment must be securely stowed. There are international standards for the ‘G force’ that securing systems must withstand in the event of a crash. In some modern road vehicles or helicopters, the requirement is 20 G. The use of a suitably engineered mount attached to the patient’s stretcher to which the equipment can be secured provides the most safety. [13]

Paediatric considerations

In general, the same principles apply to adult transfers. The use of a specialist retrieval team is associated with improved outcomes. [14] There needs to be appropriately sized equipment for all patients likely to be encountered. It is also important that there is a means to safely restrain patients in the transport vehicle. For very small patients thermoregulation is also of critical importance. In this group a dedicated transport cot provides both safe restraint and environmental control. Inclusion of a parent or carer is important and ideally, all transport platforms will allow the transfer of a parent or carer with the child. Awareness of paediatric drug dosing and easy access to a dose calculator are essential, as is an established mechanism to access specific life-saving medication, for example, alprostadil for suspected critical congenital heart disease.

Monitoring

Clinical observation by experienced clinicians remains an important facet of monitoring. [15] However, there are significant limitations to this approach. It is difficult to auscultate adequately in a moving vehicle and impossible in a helicopter. As a minimum, ECG, pulse oximetry and noninvasive BP measurement must be provided with the addition of $ETCO_2$ for any intubated patient. Noninvasive BP measurements are often subject to interference, and for critically ill patients invasive arterial access is essential, especially if the length of the transport is long. [16] Newer monitors that combine defibrillation and pacing with the monitoring aspects outlined above may be an advantage. However, noninvasive BP and defibrillation use significant battery power and spare batteries are essential and must be carried. Portable blood gas analysers provide additional management information during long transports.

Ventilators

A mechanical ventilator must be used on all intubated patients as manual ventilation cannot reliably deliver constant tidal volumes and a stable ETCO $_2$.[17] However, a manual system must be available in the rare event of a ventilator failure. Transport ventilators are a compromise between portability and features. Over the last 10 years, the desired features (as listed in Box 7.2) have almost been met. Neonates and small infants often still require a specific ventilator; at the very least they require specialised circuits and ventilator software.

Box 7.2

Features of an ideal transport ventilator

- Small, light, robust and cheap
- Not dependent on the external power source
- Turbine driven (can function without high pressure oxygen)
- Easy to use and clean, with intuitive assembly
- Economical on gas consumption
- Suitable for all patients from neonates through to adults
- $F\mathrm{i}_{O2}$ continuously variable from ambient air to 100% oxygen
- Able to deliver PEEP, CPAP, synchronous intermittent mandatory ventilation (SIMV) and pressure support
- Ability to deliver noninvasive ventilation with leak compensation and low work of breathing
- Variable I:E ratios
- Flow or pressure generator modes
- Integrated monitoring and alarm functions with audio and visual signals
- Altitude compensated

The provision of noninvasive ventilation (NIV) is now possible on most modern transport ventilators. Improvements in technology have resulted in substantial reductions in circuit work with concurrent reductions in the work of breathing. Most patients will tolerate NIV with modern ventilators,[18] but it does require a different approach by retrieval teams. There needs to be a period of observation prior to transport as the ability to provide advanced airway support in transit is limited. Modern NIV ventilators can compensate for a large circuit leak resulting in high gas consumption increasing the risk of depleting oxygen supplies. Attention to mask fit is critical to control circuit leaks and to optimise patient-ventilator synchrony. Gas consumption must be monitored, reducing the inspired oxygen fraction (FiO_2), if feasible and safe, will also assist in conserving oxygen supplies.

High-flow oxygen therapy is increasingly used for a variety of indications in both adult and paediatric patients. Although some transport ventilators can deliver the treatment, careful consideration of the available oxygen supplies is required given the obligatory very high gas consumption.

In most cases, heat moisture exchangers (HMEs) will provide adequate humidification for intubated patients.

A suction system and reserve are required. In most transport vehicles this can be provided by electrically powered devices with a gas-powered venturi system as a backup.

Infusions

Critically ill patients often need multiple infusions to be continued during transport. Some drugs that ideally should be given as infusions can be consolidated by combining sedation drugs, or the infusion stopped and given instead by frequent boluses. The older-style volumetric and drop-counting pumps have been superseded by lightweight syringe drivers, which should be the only method used for drug infusions in contemporary retrieval practice.

Intra-Aortic Balloon Pump and Extracorporeal Membrane Oxygenation

Retrieval of patients with an intra-aortic balloon pump (IABP) in situ has been occurring for many years and, in general, a team with some experience in troubleshooting any pump alarms can manage these patients. The IABP machines are reasonably bulky and heavy with an internal battery life of 1–2 hours. The type of transport vehicle has to be considered to ensure that the pump can be safely secured and can be connected to an external power source.

The H1N1 influenza pandemic in 2009–2010 saw the rapid emergence of extracorporeal membrane oxygenation (ECMO) as a valid treatment for severe viral-induced respiratory failure. [19] It was recognised that ECMO should be provided in a relatively small number of institutions, and that, ideally, patients likely to need ECMO should be transferred early. However, significant numbers of patients deteriorated rapidly and rescue ECMO was instituted in many non-ECMO centres, hence requiring the patient to be transported on ECMO. Many ECMO centre staff will not be familiar with the retrieval environment. A common model to move such patients is to combine the ECMO team with a standard retrieval team. In these cases the role of the retrieval team is to assist by providing the logistical and interhospital expertise to allow the ECMO team to concentrate on caring for the patient. More recently, the COVID pandemic has demonstrated there is still a requirement to transfer patients to ensure access to very specialised treatments such as ECMO. [20]

Mode of Transport

There are three common types of transport vehicles used: road vehicles, aeroplanes (fixed wing) and helicopters (rotary wing). The basic requirements are listed in Box 7.3 and their features and limitations are summarised in Table 7.1 .

Box 7.3

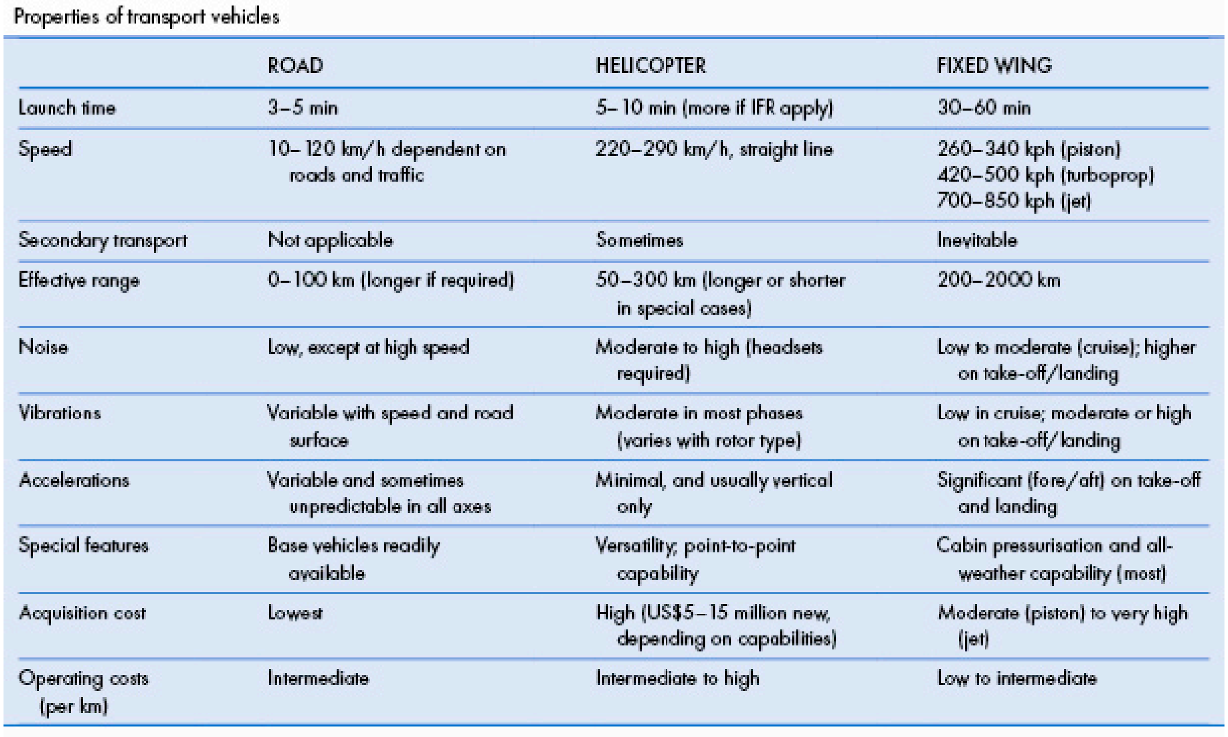
Essential features of transport vehicles

- Readily available

- Adequate operational safety
- Capable of carrying (at least one) stretcher and mobile intensive care equipment set
- Safe seating for full medical team, including at head and side of patient
- Adequate space and patient access for observation and procedures
- Equipped with adequate supply of oxygen/other gases for duration of transports
- Fitted with medical power supply of appropriate voltage and current capacity
- Appropriate speed (coupled with) comfortable ride, without undue exposure to accelerations in any axis
- Acceptable noise and vibration levels
- Adequate cabin lighting, ventilation and climate control
- Fitted with overhead IV hooks, and sharps/biohazard waste receptacles
- Straightforward embarkation and disembarkation of patient and team
- Fitted with appropriate radios and mobile telephone

IV , Intravenous.

Table 7.1



Properties of transport vehicles

	ROAD	HELICOPTER	FIXED WING
Launch time	3–5 min	5–10 min (more if IFR apply)	30–60 min
Speed	10–120 km/h dependent on roads and traffic	220–290 km/h, straight line	260–340 kph (piston) 420–500 kph (turboprop) 700–850 kph (jet)
Secondary transport	Not applicable	Sometimes	Inevitable
Effective range	0–100 km (longer if required)	50–300 km (longer or shorter in special cases)	200–2000 km
Noise	Low, except at high speed	Moderate to high (headsets required)	Low to moderate (cruise); higher on take-off/landing
Vibrations	Variable with speed and road surface	Moderate in most phases (varies with rotor type)	Low in cruise; moderate or high on take-off/landing
Accelerations	Variable and sometimes unpredictable in all axes	Minimal, and usually vertical only	Significant (fore/aft) on take-off and landing
Special features	Base vehicles readily available	Versatility; point-to-point capability	Cabin pressurisation and all-weather capability (most)
Acquisition cost	Lowest	High (US$5–15 million new, depending on capabilities)	Moderate (piston) to very high (jet)
Operating costs (per km)	Intermediate	Intermediate to high	Low to intermediate

IFR , Instrument flight rules.

Bariatric patients require specific consideration as most transport platforms have limits on the patient girth and weight that can be carried. Transport platform limitations mean that patients are often considered ‘bariatric’ at a lower weight than they would be in a hospital. Patient weight is a particular concern for aeromedical platforms where aircraft weight and balance are critical for flight safety. Furthermore, the stretcher and restraint need to be rated for the load carried and the practicalities and safety of loading and caring for a patient in the confined cabin need to be considered. At times an alternate transport mode may be required.

Ideally, dedicated vehicles should be used. Often the workload is insufficient to justify this, and nondedicated vehicles needing to be reconfigured are used. The mode of transport is based on a number of criteria:

- The availability of the transport vehicle
- The weather, especially if flying
- The distance to be travelled
- The location and capability of the retrieval team
- The urgency of the case
- The clinical capability of the referring hospital.

The coordination and tasking centre takes all these into consideration. All things being equal, the road is used for distances up to 60 km, rotary wing for 60–200 km and fixed wing for over 200 km.

Road Ambulance

This remains the most common form of transport and for some patients the safest, even for long distances.

Fixed Wing

Both propeller-driven and jet aircraft are used. Compared with helicopters, their faster speed needs to be offset against the need for a road leg at each end of the transfer. In comparison to helicopters, fixed-wing aircraft have lower cabin noise, the ability to pressurise the cabin (often to sea level), and the ability to fly in ‘icing’ conditions that increase their utility. Most aeromedical fixed-wing aircraft are specifically configured with stretcher-loading devices to assist in loading. Jets tend to be reserved for longer distances, greater than 800–1000 km.

Helicopters

These remain the most high-profile and expensive vehicles used for patient transport but have been shown to be beneficial and cost-effective.[11, 21] Most will require significant adaption to provide a reasonable working space. The lack of space makes procedures such as intubation almost impossible. They are very noisy to work in, with conversation only possible via intercom systems. This makes communication with patients difficult. Whereas a mix of single-engine and twin-engine aircraft have been used in the past, changes by regulatory authorities in Europe and Australia mean that most helicopter transports are now being performed in more suitable, larger twin-engine aircraft. The optimal range for use is a ‘donut’ of 40–300 km and their main advantage is the ability to land on hospital helipads, removing an additional road leg. This, of course, requires the hospital to have a helipad. Helicopters may also have a role in the delivery of retrieval teams to trauma cases in high-traffic-density areas, such as London.

Safety

Any mode of transport involves some risk to patients and staff. In the aeromedical environment, unfamiliar personnel perform clinical tasks poorly, [22] so teams must be appropriately trained and equipped to function effectively and safely in each mode of transport. A senior member of the professional group concerned should train and mentor new personnel on their first few trips.

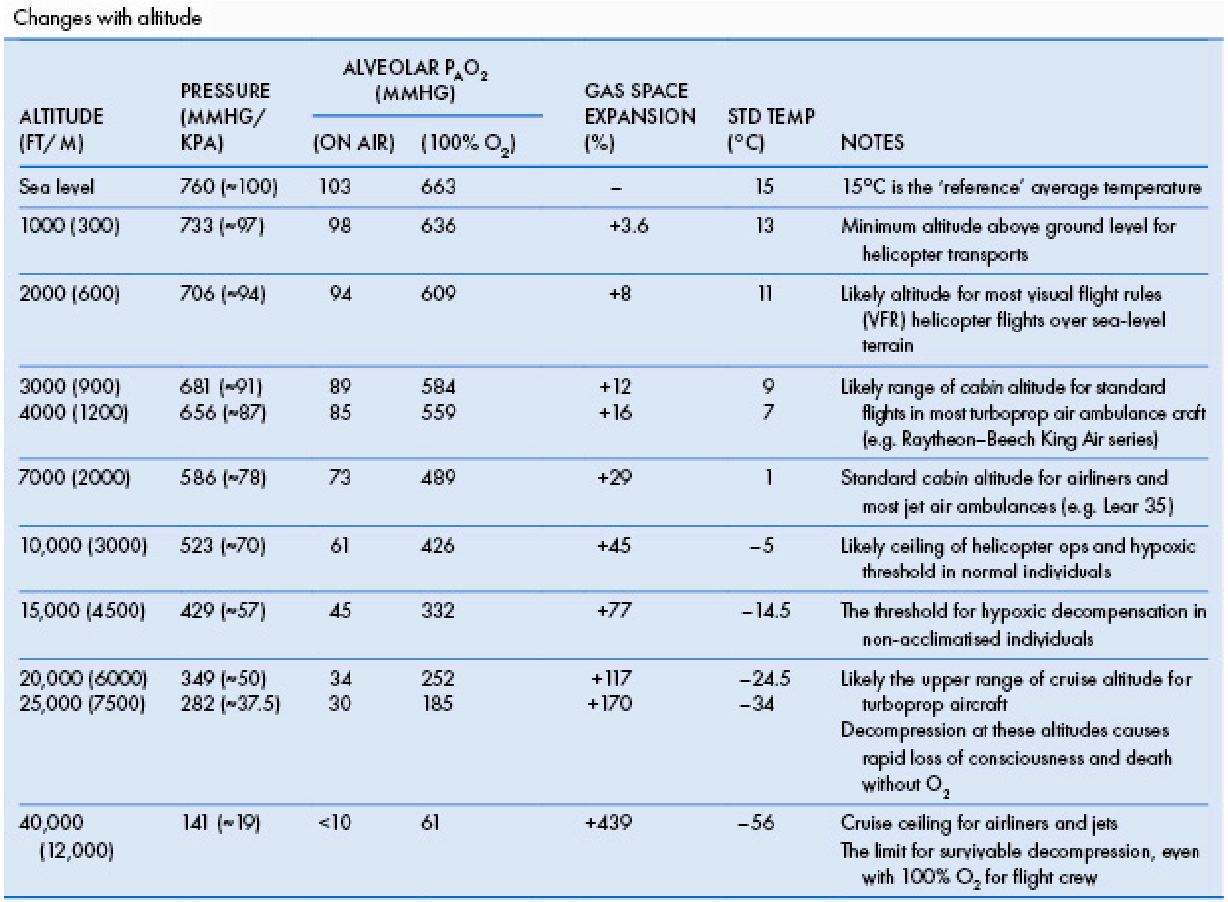
A safety brief encompassing the use of safety equipment carried on the aircraft, emergency egress and actions to take during an emergency is essential. Daily meetings with helicopter flight crews can improve communication between all members of the team.

Dangerous activities, such as unsafe driving and flying below safe minima, are unacceptable. For aviation missions, the decision whether a mission proceeds rests entirely with the aircraft pilot, and attempts to coerce pilots to take risks have been recognised as a contributor to air ambulance accidents. [23] The pilot should be provided with only the details of where the team needs to go. Clinical details should generally not be given as this may influence the decision to proceed with the mission.

Altitude and Transport Physiology

Teams need to be aware of altitude-related changes in gas, volume, temperature and partial pressures of oxygen (Table 7.2).

Table 7.2



Changes with altitude

ALTITUDE (FT/ M)	PRESSURE (MMHG/ KPA)	ALVEOLAR P_AO_2 (MMHG)		GAS SPACE EXPANSION (%)	STD TEMP (°C)	NOTES
		(ON AIR)	(100% O_2)			
Sea level	760 (~100)	103	663	–	15	15°C is the 'reference' average temperature
1000 (300)	733 (~97)	98	636	+3.6	13	Minimum altitude above ground level for helicopter transports
2000 (600)	706 (~94)	94	609	+8	11	Likely altitude for most visual flight rules (VFR) helicopter flights over sea-level terrain
3000 (900) 4000 (1200)	681 (~91) 656 (~87)	89 85	584 559	+12 +16	9 7	Likely range of cabin altitude for standard flights in most turboprop air ambulance craft (e.g. Raytheon–Beech King Air series)
7000 (2000)	586 (~78)	73	489	+29	1	Standard cabin altitude for airliners and most jet air ambulances (e.g. Lear 35)
10,000 (3000)	523 (~70)	61	426	+45	–5	Likely ceiling of helicopter ops and hypoxic threshold in normal individuals
15,000 (4500)	429 (~57)	45	332	+77	–14.5	The threshold for hypoxic decompensation in non-acclimatised individuals
20,000 (6000) 25,000 (7500)	349 (~50) 282 (~37.5)	34 30	252 185	+117 +170	–24.5 –34	Likely the upper range of cruise altitude for turboprop aircraft Decompression at these altitudes causes rapid loss of consciousness and death without O_2
40,000 (12,000)	141 (~19)	<10	61	+439	–56	Cruise ceiling for airliners and jets The limit for survivable decompression, even with 100% O_2 for flight crew

As altitude increases the ambient pressure decreases, this means that for a given fraction of inspired oxygen, the inspired partial pressure of oxygen is reduced. Patients already dependent on oxygen will be further compromised by even modest increases in height requiring further oxygen supplementation. Monitoring of SpO_2 during ascent is essential.

Gas Expansion

Expansion of trapped gas in accordance with Boyle's law occurs in physiological and pathological air spaces and air-containing equipment such as endotracheal or tracheostomy tube cuffs and Sengstaken–Blakemore tube balloons. Ideally, endotracheal tube cuff pressures should be monitored during flight, particularly during ascent and descent. Delivered tidal volumes may increase spontaneously in some older ventilators, necessitating setting adjustments.

Physiological air spaces include the middle ear, nasal sinuses and GI tract. They can affect both patients and staff; consequently, staff with upper respiratory tract infections or GI disturbances should not fly.

Pathological air spaces include pneumothoraces, emphysematous lung bullae, intraocular and intracranial open injuries, bowel obstructions and gas emboli. These patients need to be transported at the lowest altitude possible. Most modern fixed-wing aircraft are capable of cabin pressurisation, which decreases hypoxia and gas expansion. The pressurisation effectively replicates flying at a lower altitude – the so-called ‘cabin altitude’. The difference between actual altitude and cabin altitude varies, with most air ambulances providing about 350 mm Hg (≈50 kPa) differential. This equates to a cabin pressure of 3000 ft (≈900 m) whilst flying at 20,000 feet (≈6000 m). Most commercial airliners fly with a cabin altitude of around 7000–9000 ft (≈2000–2700 m). Once the maximum differential is reached, a lower altitude cabin pressure can only be achieved by flying lower, which is often associated with more turbulence and increased fuel consumption. The medical team should only request a lower cabin height if clinically indicated.

The temperature falls 2°C for every 1000 ft (≈300 m) increase in height, as does the partial pressure of water, which is not corrected by cabin pressurisation. This can lead to dehydration, especially on long trips.

Preparation for Transport

The preparation phase for transport will depend on the patient’s clinical condition. The ideal is to spend sufficient time, including any urgent surgery, stabilising the patient so that the transport phase is uneventful. As with intrahospital transport, this ideal may not be achievable, especially when the patient requires a time-critical intervention available only at the receiving destination. These missions are higher risk but are likely to be less futile than trying to stabilise an inevitably deteriorating patient. Prior to transport, all patients must have a secure airway, either self-maintained or intubated and ventilated and well-secured IV access. External bleeding should be controlled, and investigations that may impact the transport should be performed, if they can be done in a short time frame. Heimlich-type valves may be attached to any chest drains rather than bulky underwater seal drain devices. The patient is transferred to the stretcher and secured with the patient's harness. Any equipment is also attached securely to the stretcher bridge. Any documentation and copies of investigations also need to be taken. A checklist for departure and transport is recommended and provided in Box 7.4 .

Box 7.4

Suggested pre-departure checklists

During the early stages of movement, special vigilance must be employed as this is the stage when equipment disconnections or physiological decompensation is likely to occur. During transport the patient is vulnerable to hypothermia, and active warming should be considered. This can be achieved either by heating the vehicle or with a variety of commercial warming devices (e.g. blankets or fluid warmers).

Cardiac Arrest During Transport

Cardiac arrest during interhospital transfer is relatively uncommon, international registries have shown a cardiac arrest rate of 0.42% during medical transport. [24] Ideally, patients should be stabilised prior to transport, however, there are a group of patients who may only be stabilised at the destination facility, for example unrelieved myocardial ischaemia, and transport of these patients remains justified despite the increased risk of cardiac arrest during transfer. At a minimum, these high-risk patients should have self-adhesive defibrillation pads attached, reliable IV access that is easily accessible during transport, immediate access to basic airway equipment and a team plan prior to departure.

Most transport vehicles will impose some limitations on the ability to perform effective cardiopulmonary resuscitation (CPR) – rescuer numbers are limited, help is not immediately available and lack of 360-degree patient access may limit the ability to perform airway management and effective CPR. These limitations are more significant in aircraft as cabin space is usually more restricted and there is not the ability to stop immediately. In an aircraft it is important to communicate with the aircrew, key information includes declaring a medical emergency, requesting permission to come off the harness and informing the pilot before charging and discharging defibrillators. Mechanical CPR devices may make it easier and safer for the retrieval team to perform CPR during transport and are now being carried by some services.

Handover

Handover to the receiving hospital is critical. Unless the patient needs immediate resuscitation there should be an opportunity for the retrieval team to have the exclusive attention of the receiving hospital. Various handover tools such as Mechanism of injury, Injuries suspected or found, Signs [vital signs] and Treatment given (MIST) are useful for trauma cases. ISOBAR has a wider application to all patient groups and is being promoted as the standard handover tool in many areas:

- I – introduction
- S – situation
- O – observations
- B – background
- A – assessment
- R – recommendations.

Retrieval teams should use the handover tool that is used in local practice. If one is not commonly used then ISOBAR will cover all the essential elements.

Pre-Hospital Care

Pre-hospital care of the acutely injured and critically ill is a complex and challenging field of medical practice. Ideally, patients should receive the most advanced required level of care at the earliest possible time, integrated with expedient transfer to the most appropriate definitive care facility. The ability to achieve this is both resource and system dependent with unique modifiers including transport platform logistics, environmental concerns and the need to integrate with other responding emergency services.

The benefits of adding a skilled critical care physician to the pre-hospital team are well recognised. [25] Service models across Australasia and Europe reflect this belief. The potential care delivered by such a team approaches or matches that only usually available in a tertiary hospital environment and may represent a ‘definitive’ requirement for the patient. However, the benefit of a physician and the safety and effectiveness of the team is maximised only if staff involved in such activities have the requisite skills and knowledge, and are familiar with the pre-hospital and retrieval environment.

Approach to the Scene and Scene Safety

In any pre-hospital emergency situation safety is the primary concern. The pre-hospital retrieval (PHR) team should adopt the ‘safe self, safe team, safe scene, safe patient’ approach. Scene assessment is critical to ensuring team, scene and, ultimately, patient safety. It begins as soon as details of the task become available; plans for approaching the scene should be made on, or prior to, arrival.

Pre-Hospital Plan

A pre-hospital plan is a continuously evolving mental plan of action that the team will make as soon as it is activated, using the information given by the tasking agency. In many cases, this initial information is vague or incomplete, which reflects the problems experienced when receiving early phone calls about an incident. Although making a plan prior to arrival with limited information has drawbacks, there are clear benefits in arriving at the incident with a strategy for scene and patient management already in place. The plan often develops as the team travels to the scene and therefore valuable time en route should not be wasted.

When at the scene, the PHR team must have the skill to listen to all members of the emergency services and weigh up their suggestions as part of the overall plan. The ambulance service is the primary provider of pre-hospital care and paramedics are likely to be very experienced. It is worthwhile remembering that the physician-based pre-hospital teams are an extension of the ambulance service and not a replacement for them.

A generic pre-hospital plan could be:

- the scene:
  - a safe approach (self, team, scene and others)
- the patient:
  - likely requirements, need for extrication, assessment and stabilisation
- the destination:
  - triage options
  - transport platform options.

By having a pre-hospital plan, the team can add structure to their actions and, in doing so, develop a shared mental model inherent in teams that function in such high-acuity, high-consequence environments.

Entrapment and Extrication

Relative entrapment is a situation in which patients are trapped because of their injuries (e.g. a broken leg with disabling pain), location (e.g. a cave) or the ambient environment (e.g. a blizzard). If it were not for these factors, they would not require help in extricating themselves.

Actual entrapment occurs when patients are physically held in a location by the structure itself; for example a major vehicle deformation with cabin intrusion, or a building collapse.

The aim is to remove the patient from an entrapped situation as safely and as quickly as possible. The key determinant in this plan (apart from safety) is the condition of the patient. The PHR team must decide on how to compromise between the slower, methodical extrication with total spinal control and the quicker extrication of the less stable patient. Clearly, unstable patients will need rapid extrication, but the ability to predict which patients are unsuitable for prolonged extrication due to the anticipated clinical course is more challenging. It may be better to compromise a degree of spinal protection earlier rather than have an emergency (‘crash’) extrication situation develop 30 minutes later.

The fire and rescue services will have access to the specialised equipment required. Without good teamwork between the services, the extrication will be significantly hindered.

Ultrasound in the Field

The availability of robust portable ultrasound machines has resulted in increased use in the pre-hospital and retrieval environment with good success; however, their use must be limited to people accredited in its use and must not result in undue delays in patient management.

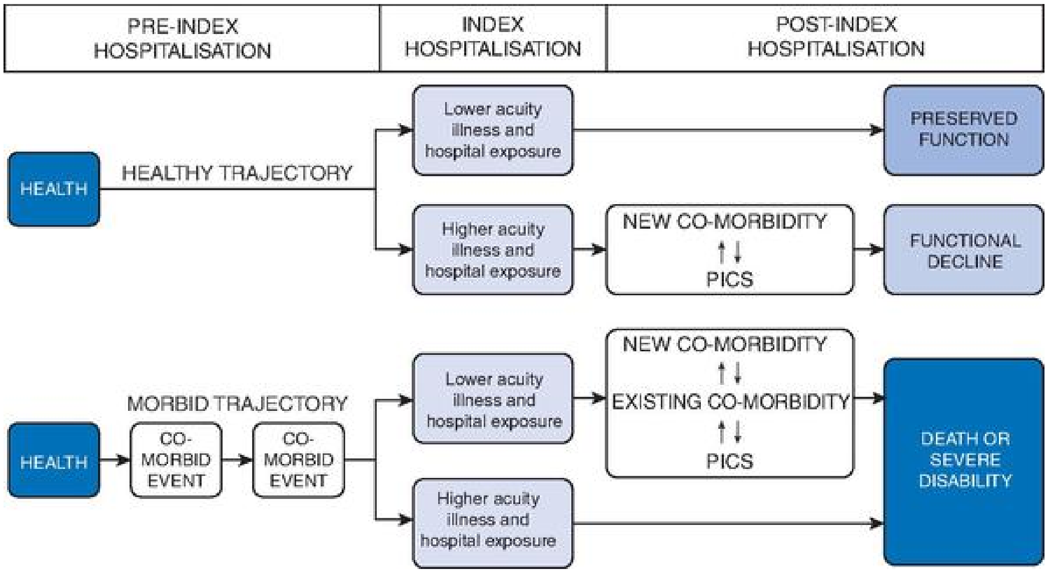
Common problems after ICU

Andrew Slack, Kate Tantam and Joel Meyer

Post-Intensive Care Syndrome (PICS)

Post-intensive care syndrome (PICS) affects between 40% and 60% of critical illness survivors and manifests as impairments across three domains: **cognitive** , **psychological** and/or **physical** function, which impact an individual's quality of life. These impairments can involve a single domain or all three with varying degrees of severity. Functional outcome is impacted by pre-hospital health, illness acuity and hospital exposure and the inter-relationship of existing and newly acquired co-morbidities on the resultant PICS symptoms (Fig. 8.1).[1]



PRE-INDEX HOSPITALISATION
INDEX HOSPITALISATION
POST-INDEX HOSPITALISATION
HEALTH
HEALTHY TRAJECTORY

CO-MORBID EVENT
Lower acuity illness and hospital exposure
NEW CO-MORBIDITY ↑↓ EXISTING CO-MORBIDITY ↑↓ PICS
Higher acuity illness and hospital exposure
DEATH OR SEVERE DISABILITY

The diagram shows three vertical sections labelled pre-index hospitalisation, index hospitalisation, and post-index hospitalisation. On the left, two horizontal paths begin from a box labelled health. The upper path is labelled healthy trajectory and continues into the index hospitalisation section, where it splits into two boxes labelled lower acuity illness and hospital exposure, and higher acuity illness and hospital exposure. The lower acuity branch leads directly to a box labelled preserved function. The higher acuity branch leads to a box labelled new co-morbidity, which contains bidirectional arrows leading to post-intensive care syndrome. This path continues to a box labelled functional decline. The lower portion of the diagram represents the morbid trajectory. From the health box, the path moves through two boxes labelled co-morbid event before reaching the index hospitalisation section. It then branches into the same two boxes as in the healthy path, labelled lower acuity illness and hospital exposure, and higher acuity illness and hospital exposure. Lower acuity illness and hospital exposure box leads to a box labelled new co-morbidity and existing co-morbidity, which also contains the bidirectional arrows along with post-intensive care syndrome. This leads to the final box labelled death or severe disability.

FIG. 8.1 Healthy and morbid trajectories for individuals suffering critical illness. (From Cuthbertson BH, Wunsch H. Long-term outcomes after critical illness. The best predictor of the future is the past. *Am J Respir Crit Care Med* . 2016;194(2):132-134.)

Physical Impairment

Intensive care unit (ICU)-acquired weakness may affect up to half of ICU survivors admitted for 1 week or more and is the result of cellular dysfunction (mitochondrial dysfunction and the release of inflammatory cytokines) along with immobility and deconditioning. Early rehabilitation is safe, but engagement may be impeded by ICU delirium and cognitive impairment.

The long-term impacts of weakness on functional recovery are exercise limitation, fatigue, joint immobility, imbalance (risk of falls) and dependency on activities of daily living. Any of the following physical impairments – shortness of breath, hair loss, voice changes, dysphagia and sexual dysfunction – can impact mental health and health-related quality of life.

Cognitive Impairment

The risk of cognitive impairment ranges from 20% to 40% and can be temporary, affecting individuals for up to 2 years or sometimes it can persist permanently. [2] The key risk factors for cognitive impairment include:

- Delirium in the ICU (especially longer duration of delirium)
- Prolonged mechanical ventilation

- Older age
- Pre-existing cognitive impairments

Identifying and managing ICU delirium during critical illness is important and includes both non-pharmacological and pharmacological interventions. Consistent implementation within the ICU of the Society of Critical Care Medicine’s ABCDEF bundle [3] and the 2018 PADIS Guidelines (Prevention and Management of Pain, Agitation/Sedation, Delirium, Immobility, and Sleep Disruption in Adult Patients in the ICU) improves long-term outcomes. [4]

- **A** ssess, Prevent, and Manage Pain;
- **B** oth Spontaneous Awakening Trials (SAT) and Spontaneous Breathing Trials (SBT);
- **C** hoice of analgesia and sedation;
- **D** elirium: Assess, Prevent, and Manage;
- **E** arly mobility and Exercise;
- **F** amily engagement and empowerment.

Strategies for the humanisation of ICU are linked to both improving patient outcome, patients’ and loved ones’ experience and reducing burnout related to intensive care [5] see Box 8.1 .

Box 8.1

Humanisation of the critical care environment

The optimisation of the patient and loved ones’ experience of critical care is embedded within delirium management. Use of therapeutic fresh air spaces, animal-assisted interventions, sleep optimisation, personalisation of the bedspace, clearly displayed holistic functional rehabilitation plans, use of personal devices and access to communication aids promote patient-centred care. Recovery after critical illness leads to care transitioning to environments outside of the critical care where there is decreased availability of staff and equipment. The de-intensification of care needs to be approached sensitively as patients and loved ones often report a feeling of ‘abandonment’. This can be managed with clear verbal and written handovers, discharge summaries, patient diaries (Box 8.3) and with continuing care from rehabilitation teams, and collaborative multi-professional inpatient care coordination.

Cognitive impairment can manifest as alterations of executive function, attention and memory, which can affect cooking, driving, managing finances, technology, use of healthcare devices, understanding social situations, returning to work and undertaking carer/parenting roles. Unidentified cognitive impairment can compromise the safety of patients and loved ones and a cognitive assessment should form part of a PICS assessment. The impact cognitive impairment has on return to work, finances and mental health are outlined in Box 8.2 .[1]

Box 8.2

What does PICS mean for your patients?

Approximately two-thirds, two-fifths and one-third of previously employed intensive care unit survivors are jobless up to 3-, 12- and 60-months following hospital discharge.[7] This has the potential to significantly impact loved ones and extended roles within family groups. Financial pressures related to changes in circumstance can lead to worsening mental health and post-intensive care syndrome in family members PICS(F). PICS(F) is experienced by family members of the intensive care unit (ICU) in response to critical illness and is characterised by new or worsening psychological symptoms.

Psychological Impairment

The most common psychological symptoms include mood changes, emotional lability, relationship changes, anxiety and depression, flashbacks, nightmares, amnesia from the ICU stay and social isolation.[2]

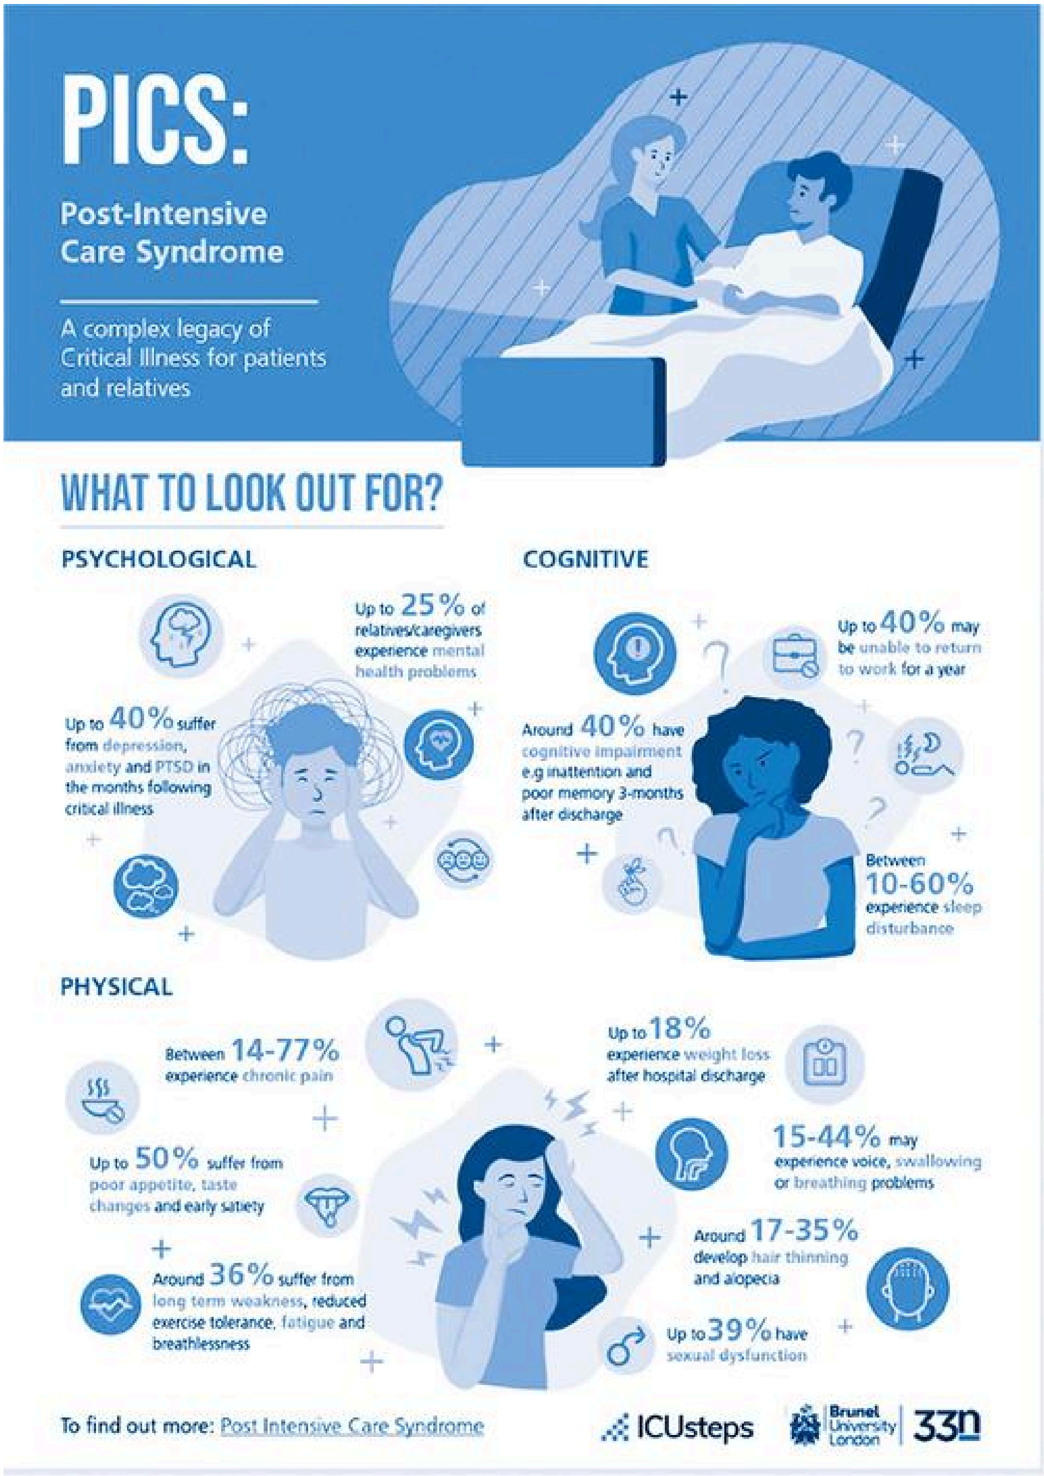
ICU patients experience:

- Anxiety (~70%)
- Depression (~33%) at 1 month after returning home[2]
- Post-traumatic stress disorder (PTSD) (10%–50%)

Clinically significant PTSD symptoms include avoidance and hyperarousal, which occur twice as frequently as intrusion symptoms (nightmares and flashbacks). The risk factors for PTSD include pre-ICU psychiatric morbidity (PTSD or depression) and use of benzodiazepines (total dose not duration) and post-ICU memories that are frightening.

Post-ICU Recovery Clinic

The key aim for any multi-professional team delivering a post-ICU recovery service role is to evaluate the degree of PICS symptoms and intervene accordingly (see Fig. 8.2). Outpatient recovery services can be consultant intensivist-led or nurse-led with support from some or all of the following allied health professionals forming the team working together to assess patients: occupational therapist, physiotherapist, psychologist, pharmacist, dietitian, speech and language therapist and liaison- or neuro-psychiatrist.



PICS:

Post-Intensive Care Syndrome

A complex legacy of Critical Illness for patients and relatives

WHAT TO LOOK OUT FOR?

PSYCHOLOGICAL

Up to 25% of relatives/caregivers experience mental health problems

Up to 40% suffer from depression, anxiety and PTSD in the months following critical illness

COGNITIVE

Up to 40% may be unable to return to work for a year

Around 40% have cognitive impairment e.g inattention and poor memory 3-months after discharge

Between 10-60% experience sleep disturbance

PHYSICAL

Between 14-77% experience chronic pain

Up to 18% experience weight loss after hospital discharge

Up to 50% suffer from poor appetite, taste changes and early satiety

15-44% may experience voice, swallowing or breathing problems

Around 36% suffer from long term weakness, reduced exercise tolerance, fatigue and breathlessness

Around 17-35% develop hair thinning and alopecia

Up to 39% have sexual dysfunction

To find out more: Post Intensive Care Syndrome

The infographic is titled P I C S with the subtitle Post-Intensive Care Syndrome, followed by the phrase A complex legacy of critical illness for patients and relatives. At the top, a drawing shows a healthcare professional standing beside a person lying in bed. Below this is a large heading stating what to look out for, followed by three labelled sections. The first section is labelled psychological and includes the following text segments. Up to 40 percent suffer from depression, anxiety, and P T S D in the months following critical illness. Up to 25 percent of relatives and caregivers experience mental health problems. The second section is labelled cognitive and includes the following statements. Around 40 percent have cognitive impairment, such as inattention and poor memory, three months after discharge. Up to 40 percent may be unable to return to work for a year. Between 10 to 60 percent experience sleep disturbance. The third section is labelled physical and lists multiple conditions. Between 14 to 77 percent experience chronic pain. Up to 50 percent suffer from poor appetite, taste changes, and early satiety. Around 36 percent suffer from long-term weakness, reduced exercise tolerance, fatigue, and breathlessness. Up to 18 percent experience weight loss after hospital discharge. Between 15 to 44 percent may experience voice, swallowing, or breathing problems. Around 17 to 35 percent develop hair thinning and alopecia. Up to 39 percent have sexual dysfunction. The bottom row includes logos of I C U steps, Brunel University London, and 33 N, along with a web link text reading To find out more Post Intensive Care Syndrome.

FIG. 8.2 PICS infographic. (Copyright ICS, ICU steps, Brunel University and 33n.)

Reducing Adverse Events after Discharge Home

Mortality and re-hospitalisation rates in the year following ICU discharge of 20% and 25% (higher in sepsis survivors) respectively, are associated with age, ICU length of stay, multi-morbidity (including mental illness and frailty) and presenting illness (sepsis). [6] Additional determinants to identify and manage which are potentially within the scope of post-ICU services include: fragile social support, domestic caring arrangements, mobility problems, multiple medications, discharge practices and exchange of information. The post-ICU outpatient phase of care may also present a first opportunity to discuss behavioural change and lifestyle interventions (smoking, alcohol intake and diet) as well as undertake anticipatory care planning including resuscitation status.

Mode of Delivery

The majority of post-ICU recovery clinics prior to the COVID-19 pandemic were delivered in person at hospital-based outpatient clinic settings or via telephone consultation. Today, video consultations have increasingly been utilised to reduce the need for patients to travel long distances and are supported by the widespread availability of smartphones. Digital literacy can impact and disadvantage some patients, so ensuring patients can choose between video or telephone for the initial consultation is important. Video consultation offers the advantage of seeing the home environment and some observation of physical impairment is possible. However, if a clinical examination is required or information gathering is challenging then face-to-face clinic visits need to be organised.

Comprehensive Evaluation of PICS

The physical review by the consultant, therapist or nurse assesses each vital organ system with a focus on the organs affected while critically ill. It is important to review skin, hair, scalp and nails. It is not uncommon to encounter delayed healing, dehisced wounds, keloid scar formation, hair loss or retained ECMO cannulae sutures. Review of pain from wounds, joints and limb neuropathies acquired in ICU must be undertaken. Referral to chronic pain services for optimisation of non-opioid analgesia and cessation of opioids needs to be considered. Sexual dysfunction and intimacy should be explored sensitively. Voice assessment for any patient with prolonged endotracheal intubation, tracheostomy or both should be undertaken to identify any new dysphonia or stridor.

Multi-Professional Team

Allied health professionals are integral to delivering ICU inpatient care and the expertise they offer is correspondingly invaluable in the outpatient recovery services. Unfortunately, funding and workforce constrain availability. Each allied health professional role is briefly outlined below.

- **Physiotherapists**

  identify global motor dysfunction, stiffness and impaired range of movement, as well as focal impairments of upper or lower limb warranting further investigation and intervention from community therapy teams. Respiratory physiotherapy (including dysfunctional breathing service) and graded resumption of exercise and activity are provided. A combined assessment with occupational therapy (OT) can be helpful as it will focus on the functional impact of any identified physical and cognitive impairment, which can inform the need for additional input from community teams that include OT and physiotherapists.
- **Occupational therapists**

  consider physical, psychological, social and environmental needs with a focus on how to support and enable key activities, such as getting out of bed in the morning, getting washed, preparing meals, resuming work or education and fulfilling caregiver and family roles.
- **Clinical psychologists**

provide brief psychological interventions acknowledging the impact of the critical illness, adapting to change, exploring anxiety triggers (including flash forward anxiety), motivational goal setting, as well as identifying patients at risk or requiring further mental health expertise.

- **Psychiatrists**

  provide expertise in complex PTSD, mood and anxiety disorders and their overlap with cognitive impairment through the conduction of neurocognitive testing, investigation, psychoactive medicines, risk assessment and management planning.
- **Pharmacists**

  provide medicines risk assessment and reconciliation across care transitions including ICU to ward and hospital to community, Box 8.3 .
- **Dietitians**

  provide nutrition assessment and support for weight loss and obesity management.
- **Speech and language therapists**

  provide voice and swallowing assessment and management.

Box 8.3

Medication review

Post-ICU medicines reconciliation by an ICU pharmacist ensures medication from the ICU or hospital admission is discontinued, omissions re-commenced, polypharmacy risks addressed and doses adjusted appropriately, for example, for changes in kidney function. It also provides an opportunity to assess allergy status; review suspected medication reactions encountered in ICU, either confirm or de-label a reported beta-lactam or vaccine allergy. A referral to allergy specialist services is warranted, especially for patients at risk of re-infection and because true beta-lactam allergy, although reported by up to 10%, is very uncommon (<1% of the adult population). [8] Vaccination history and eligibility are documented.

Box 8.4

Patient ICU diaries

Memory gaps in ICU survivors are associated with psychological distress. ICU diaries have a role to improve the patient's factual memory of the ICU and reduce the risk of depression and preserve the quality of life. [13] These can include photographs, text and loved ones are encouraged to add to these documents.

Explanation of ICU Events

Many patients derive benefit from receiving a verbal description or timeline of events and interventions undergone during their ICU care. Discharge summaries and ICU diaries provide a record of the ICU events and clinical course, with the latter a more personalised account of events.

ICU diaries were first utilised in Denmark in the 1980s and the 1990s in the United Kingdom. ICU diaries are digital or paper records of daily encounters with staff, family or carers where personal messages or significant events are recorded. Qualitative studies report that patients and relatives generally welcome the diary as they are able to evaluate their ICU experiences, understanding their perceptions of their dreams during their period of critical illness, and their intensive care experiences which they previously failed to understand. The provision of a diary may help psychological recovery in patients' families after critical illness. [9]

Open discussions on ICU, inpatient and community experiences can often support patients to disclose psychological symptoms. Video walk-rounds or in-person visits back to the ICU can be beneficial in supporting patients and loved ones with contextualisation of ICU events.

Onward Referrals

Outstanding medical and surgical interventions, investigations, treatments or follow-ups should be completed. In the United Kingdom, commissioned services are responsible for the investigations, referrals and management and do not rely solely on the general practitioner (GP) to complete. There are times when direct liaison with the patient's GP can be helpful to plan community-based interventions. Many have links to community mental health, chronic pain services, social prescribing and district nurse provision.

Patient-Centred Approach

Holistic patient-centred interventions, in partnership with loved ones, are fundamental for reducing the overall burden of symptoms of PICS and improving quality of life. The post-ICU team often fulfils a unique role in advocating for the patient and signposting their exceptional needs, especially if they cannot advocate for themselves. This ensures post-ICU patients are appropriately prioritised by physical and mental health services.

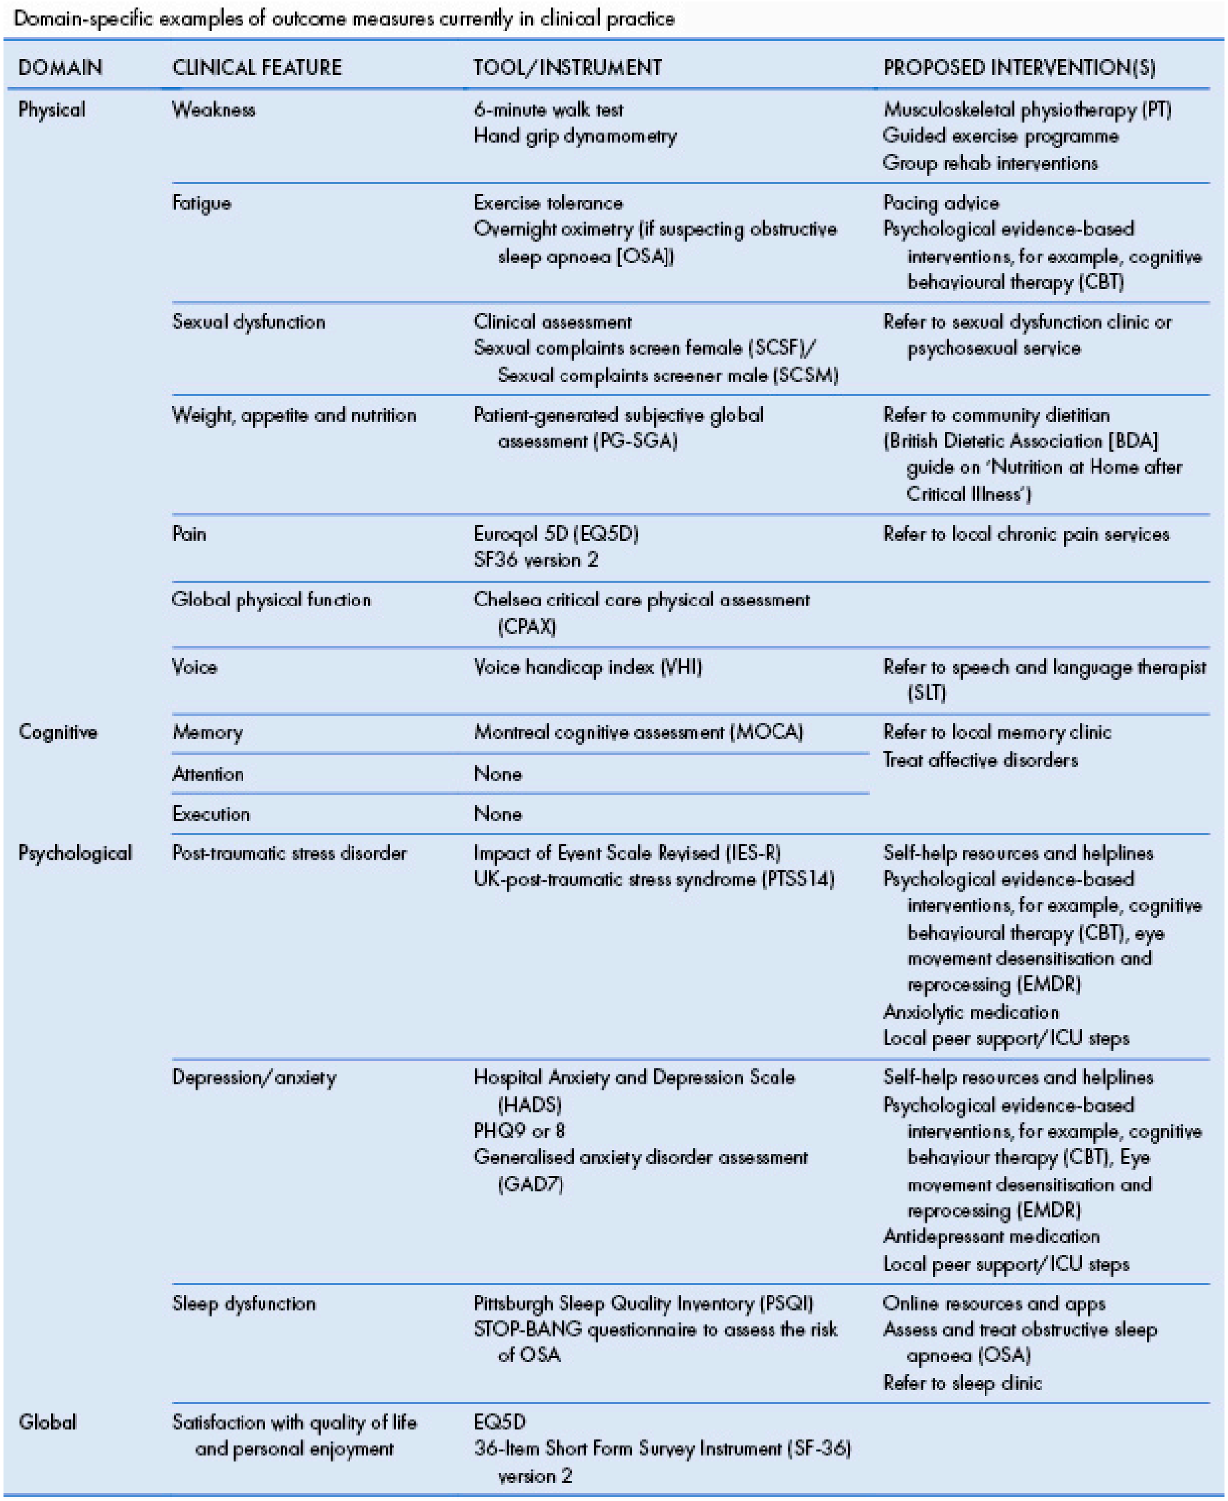
Striking a suitable balance between hospital and community healthcare utilisation requires careful consideration and sometimes liaison with the patient's community services to determine the best option. Hospital-based interventions may require planned interpreter and transport services along with instructions on reimbursement processes if travelling to the hospital and in receipt of income support.

Not every eligible patient will successfully engage with the offered service. Safety netting for this vulnerable cohort could include a phone call to the community healthcare provider and recorded next-of-kin, reminder letters and flexible re-referral policy via a single point of contact.

Clinical Use of Outcome Measures

The assessment of PICS can be supported by routine self-reported measures and instruments although not all are validated for post-ICU patients.[10] Examples are given in Table 8.1 . The quantitative scores can be useful to track patient trajectory, guide service provision and support referrals to specialist community services. In the United Kingdom, the PHQ8 or 9 and GAD7 questionnaires for depression and anxiety, respectively, are used to access NHS Talking therapy services (see Table 8.1).

Table 8.1



Domain-specific examples of outcome measures currently in clinical practice

DOMAIN	CLINICAL FEATURE	TOOL/INSTRUMENT	PROPOSED INTERVENTION(S)
Physical	Weakness	6-minute walk test Hand grip dynamometry	Musculoskeletal physiotherapy (PT) Guided exercise programme Group rehab interventions
	Fatigue	Exercise tolerance Overnight oximetry (if suspecting obstructive sleep apnoea [OSA])	Pacing advice Psychological evidence-based interventions, for example, cognitive behavioural therapy (CBT)
	Sexual dysfunction	Clinical assessment Sexual complaints screen female (SCSF)/ Sexual complaints screener male (SCSM)	Refer to sexual dysfunction clinic or psychosexual service
	Weight, appetite and nutrition	Patient-generated subjective global assessment (PG-SGA)	Refer to community dietitian (British Dietetic Association [BDA] guide on 'Nutrition at Home after Critical Illness')
	Pain	Euroqol 5D (EQ5D) SF36 version 2	Refer to local chronic pain services
	Global physical function	Chelsea critical care physical assessment (CPAX)	
	Voice	Voice handicap index (VHI)	Refer to speech and language therapist (SLT)
Cognitive	Memory	Montreal cognitive assessment (MOCA)	Refer to local memory clinic Treat affective disorders
	Attention	None	
	Execution	None	
Psychological	Post-traumatic stress disorder	Impact of Event Scale Revised (IES-R) UK-post-traumatic stress syndrome (PTSS14)	Self-help resources and helplines Psychological evidence-based interventions, for example, cognitive behavioural therapy (CBT), eye movement desensitisation and reprocessing (EMDR) Anxiolytic medication Local peer support/ICU steps
	Depression/anxiety	Hospital Anxiety and Depression Scale (HADS) PHQ9 or 8 Generalised anxiety disorder assessment (GAD7)	Self-help resources and helplines Psychological evidence-based interventions, for example, cognitive behaviour therapy (CBT), Eye movement desensitisation and reprocessing (EMDR) Antidepressant medication Local peer support/ICU steps
	Sleep dysfunction	Pittsburgh Sleep Quality Inventory (PSQI) STOP-BANG questionnaire to assess the risk of OSA	Online resources and apps Assess and treat obstructive sleep apnoea (OSA) Refer to sleep clinic
Global	Satisfaction with quality of life and personal enjoyment	EQ5D 36-Item Short Form Survey Instrument (SF-36) version 2	

Online, Social Media and Self-Help Resources

There is a vast amount of online self-help information available and many helpful organisations to support patients, families and carers in the post-ICU recovery period to which post-ICU recovery services should signpost. Multiple social media patient-led groups and virtual peer support programmes are emerging. Digital-enabled therapies (DET) for psychological conditions are available.

  - https://www.sccm.org/MyICUCare/THRIVE
- Self-help for mental health including sleep problems:
  - https://www.nhs.uk/every-mind-matters/

Condition-specific standardised advice is often helpful to share with patients, families and carers:

- Post-AKI (acute kidney injury) care signposting to the risks of chronic kidney disease and the need for kidney function surveillance
- Fatigue management strategies including pacing
- Citizens Advice Bureau for social services and income support advice
- Driving resumption advice – consult the Driver and Vehicle Licensing Agency (DVLA) guidance, which covers notifiable conditions and safe resumption
- Airline flight advice
- Return to work
- Vaccinations

Post-Intensive Care Syndrome – Family (PICS-F)

Families of critically ill patients may suffer from significant psychological distress, affecting 25% to 50% of family members, with a third of families taking medication for depression or anxiety.[11] The psychological distress can include:

- Anxiety 10%–75%
- Post-traumatic distress syndrome 8%–42%
- Depression
- Sleep disturbance
- Complicated grief

PICS-F Interventions

Evidence supports interventions during the ICU stay to mitigate these PICS-F symptoms,[11],[12] which include:

- The use of family educational materials
- Family meetings
- Enhanced team communication
- ICU diaries (Box 8.4)
- Family engagement on rounds
- Family presence during cardiopulmonary resuscitation and invasive procedures
- Attendance at post-ICU recovery clinics and support groups

Caregiver/Family Member Outcomes

Family and carers experience a significant impact on their attendance at work and this translates to an associated financial burden. Several reports have highlighted the changes in employment status with reduced hours, job changes and lost earnings. These work and finance issues add to the burden of anxiety.[14]

Clinical assessment of the critically ill patient

Jeremy Cohen, Mary Pinder and Bala Venkatesh

Introduction

To those approaching the practice of intensive care medicine for the first time, it might seem that physical examination (PE) of the critically ill patient has only a limited role. After all, our patients are often inaccessible, obscured by dressings or devices, uncooperative, or too unstable to move. Furthermore, some might argue that the information provided by the many bedside monitors, invasive measuring devices or readily available imaging techniques provides enough information to the clinician such that PE of the patient becomes no longer necessary. There is some evidence that this view is not uncommon; a survey of 122 practitioners on medical intensive care unit teams found that half of them considered PE not to be useful.[1] A review of 30 textbooks dealing with clinical assessment found that none of them had a section on examination of the critically ill patients.[2] An alternative viewpoint is that a rigorous PE, performed at least once a day, forms an essential part of the assessment of every patient in intensive care, and can provide information not necessarily available from laboratory tests, monitors or imaging. However, a standard PE as traditionally taught, is not always possible in critically ill patients. In this chapter, we will discuss the role and limitations of physical assessment in the critically ill, highlighting an essential skill for all intensive care physicians.

Physical Examination in the Critically Ill: Importance and Limitations

Physical examination (PE) is taught in medical schools as an essential step in diagnosis and assessment, but is often focussed on an ambulatory, stable patient in whom a detailed history is available, and practitioners have the luxury of time to order and review investigations. The role of PE in critically ill patients has been less well studied, although evidence exists to support its usefulness. A study examining the use of PE in consecutive patients admitted to an emergency department demonstrated that PE doubled the diagnostic power of the history, and that 80% of all cases could be correctly diagnosed with history and PE alone. [3] Some clinical signs in critically ill patients have been shown to correlate with sickness severity and potentially identify patients at risk of deterioration. [4,5] However, controlling for the experience of the examiner remains a significant obstacle in performing studies in this area, and robust data linking PE with outcomes in critically ill patients do not exist. Nevertheless, there are compelling arguments for performing regular bedside evaluations on the critically ill. There are concerns that the increasing use of looking only at the patient chart, or the numerous tests and investigations, create what has been dubbed an ‘iPatient’; a facsimile of reality in which cutting and pasting disease labels into patient notes makes them immutable, and results of investigations are interpreted without context. [6] A study of intensive care unit (ICU) physicians using electronic medical records determined that over 80% of all notes contained more than 20% copied information. [7] The practice of regular bedside PE ensures that new findings are not missed and that diagnoses that exist only in the patient’s notes are not perpetuated. The role of PE in strengthening the doctor-patient relationship, in improving clinical skills and knowledge and avoiding unnecessary or expensive investigations has also been highlighted. [6] PE is part of the summative assessment process for intensive care training and needs to be a skill that is practised and refined on a daily basis and not just performed in the context of an assessment.

The relative advantages and disadvantages of physical examination in the critically ill are summarised in Table 9.1 .

Table 9.1

Physical examination in intensive care

Advantages
Cheap, simple
Can be repeated
Can be performed by personnel of diverse experience and training
Findings can be informed by bedside monitors
Validates (or not) information from monitoring
Can be performed in situ
Less inconvenience or distress to sedated patients
May prevent unnecessary or invasive tests
Enhances clinician-patient relationship and promotes empathy
May direct selection of definitive investigations
Disadvantages
Sedated patients cannot report discomfort or pain on examination
The performance and reliability of many physical signs are not established in the critically ill population
Patients often cannot be moved into optimum position for physical examination
Dressings may impair access to the patient (e.g. burns)
Neurological examination may be clouded by sedation or neuromuscular paralysis
Noise levels in ICU are a barrier to obtaining information from auscultation

May be inferior to information obtained from other bedside investigations, e.g., ultrasound

Approaches to Physical Examination in the Critically Ill

It should be emphasised that there is no ‘one size fits all’ approach to examining a critically ill patient. The salient points of examination in a patient with Guillain Barre syndrome, for example, would be quite different from those in a patient with septic shock. A common error in trainees is to apply a rigid framework to their examination process without adapting to the patients’ particular circumstances. With that in mind, we have provided a simple general framework for an approach to a stable, ventilated patient in intensive care, as well as some more specific guidance for particular clinical scenarios. Of note, this approach is not intended to supplant the standard clinical examination, but rather to complement it. PE techniques, such as cardiac auscultation, or palpation of abdominal viscera should still be performed as normal. Examination for particular constellations of physical signs, such as in chronic liver disease, or infective endocarditis should be performed as indicated.

General Approach to Stable, Ventilated Patient

Introduce yourself to the patient, tell them what you are going to do and seek assent if appropriate.

Observation around the bedspace

- Check monitor – vital signs.
- Check infusions – type, dose, trend.
- Check ventilator settings – mode, measured parameters, inspired oxygen concentration.
- Check extracorporeal circuits (CVVHDF, ECMO).

- Check drains – type and volume of drainage including nasogastric, urine, cerebrospinal fluid (CSF).

Structured Physical Examination

General observation : For comfort, nutritional status, restraints, etc.

In patients who are sedated, or not obviously awake, perform an initial brief assessment to establish the level of consciousness. Consider pausing or decreasing sedation to allow for a more meaningful assessment of the neurological status later in the examination.

Hands and upper limbs : Particular attention should be paid to peripheral perfusion, and asymmetrical swelling or mottling that may indicate upper limb venous thrombosis or soft tissue infection. Inpsect the site of a radial arterial line if present.

Head and neck : Note movement restrictions especially in patients with trauma. Examine for pupillary responses, facial symmetry and the presence of a nasogastric or orogastric tube. Jugular venous pressure may not be assessable if the patients' position is restricted. Note central venous access sites and cervical spine stabilisation methods as appropriate.

Note the size, securement method and length of either the endotracheal tube or tracheostomy tube if present. Listen for a tracheal cuff leak.

A formal tracheal cuff leak test can be performed by removing the air from the cuff and either listening for an audible leak, or checking for volume loss with quantitative methods. Data suggests that the tracheal cuff leak test has a high specificity for post-extubation stridor and risk of reintubation, but only moderate sensitivity. [8] Clinical practice guidelines from the American Thoracic Society recommend that a cuff leak test be performed prior to extubation only in mechanically ventilated adults who are deemed high risk for post-extubation stridor. [9]

Chest and precordium : Perform a standard cardiorespiratory examination as is practical. Particular consideration should be paid to the patient's respiratory efforts and ventilator synchrony. Signs of endobronchial intubation, pneumothorax and subcutaneous emphysema should be sought as particular complications of mechanically ventilated patients. Note the nature and volume of any endotracheal tube secretions.

Note the presence of thoracostomy tubes, and the nature and volume of drainage, as well as swing, and air leak. Examination of the ventilator waveform can provide valuable information, including the presence of and discrimination between upper and lower airway obstruction, as well as patient-ventilator dyssynchrony (see Chapter 39 , Mechanical Ventilation Waveforms for further details). Physical signs that are augmented in a particular phase of the respiratory cycle (e.g. the murmur of tricuspid regurgitation being louder, or splitting of the second heart sound being greater in inspiration) will have these findings occur in the opposite phase in patients receiving mechanical ventilation.

Abdomen : In addition to a standard abdominal examination including inspection, percussion, and palpation, enquire as to the route of feeding, nasogastric drainage and bowel movements, including the presence of blood or melaena. Perform an inspection of the groins, especially for vascular access sites or sites of angiography. The role of routinely listening for bowel sounds in a critically ill patient is controversial, with clinical reviews suggesting that the presence or absence of bowel sounds gives little relevant information. [10] Intra-abdominal pressure measurement should be performed if appropriate.

Neurological examination : This raises particular challenges in intensive care patients, both due to the multiple confounding features that may be present (sedation, neuromuscular paralysis, delirium) and as the nature of the examination performed is determined by the level of consciousness of the patient. [11]

In conscious patients the neurological examination may be performed in a routine manner, examining orientation, cranial nerves, limb tone, power and sensation and deep tendon reflexes. However, not all parts may be practical, and detailed assessments such as visual fields, Weber and Rinne tests, or in-depth sensory testing are rarely, if ever, indicated. In patients who are sedated but able to co-operate with this type of examination, the sedation may be interrupted at the examiner's discretion, although this is not recommended for patients with raised intracranial pressures or in whom removal of sedation may lead to other deleterious effects.

In comatose patients, attention is primarily directed at determining the level of neurological alertness using standard scales (Table 9.2). Brainstem function should be evaluated by examination of the accessible cranial nerves, as well as respiratory pattern or signs of diabetes insipidus. The motor response should be examined in all limbs. If brain death is suspected, then testing should proceed using approved protocols (see Chapter 14 , Determination of Death in ICU for further detail).

Table 9.2

Glasgow Coma score and FOUR score

FOUR SCORE	GLASGOW COMA SCORE
Eye response	**Eye response**
4 Eyelids open or opened, tracking, or blinking to command	4 Eyes open spontaneously
3 Eyelids open but not tracking	3 Eye opening to verbal command
2 Eyelids closed but open to loud voice	2 Eye opening to pain
1 Eyelids closed but open to pain	1 No eye opening
0 Eyelids remain closed with pain	
Motor response	**Motor response**
4 Thumbs-up, fist or peace sign	6 Obeys commands
3 Localising to pain	5 Localising to pain
2 Flexion response to pain	4 Withdrawal from pain
1 Extension response to pain	3 Flexion response to pain
0 No response to pain or generalised myoclonus status	2 Extension response to pain
	1 No motor response
Brainstem reflexes	**Verbal response**
4 Pupil and corneal reflexes present	5 Oriented
3 One pupil wide and fixed	4 Confused
2 Pupil or corneal reflexes absent	3 Inappropriate words
1 Pupil and corneal reflexes absent	2 Incomprehensible sounds

FOUR SCORE	**GLASGOW COMA SCORE**
0 Absent pupil, corneal, and cough reflex	1 No verbal response
Respiration	
4 Not intubated, regular breathing pattern	
3 Not intubated, Cheyne–Stokes breathing pattern	
2 Not intubated, irregular breathing	
1 Breathes above ventilator rate	
0 Breathes at ventilator rate or apnoea	

In patients with traumatic brain injury examine for signs of basal skull fracture; bruising around the eyes (‘raccoon eyes’), bruising over the mastoid process (Battle sign), CSF otorrhoea or rhinorrhoea. Confirmation that a discharge is CSF can be obtained by analysis for Tau protein/ß2 Transferrin. Attention should be paid to intracranial pressure monitors, cerebral perfusion pressure and external ventricular drainage as appropriate. A full or tense craniectomy flap may also indicate a rise in intracranial pressure.

The pupillary reflexes are one of the most useful signs for both identifying the site of a lesion and in differentiating between metabolic and structural causes of coma. A unilateral dilated pupil in a comatose patient usually indicates temporal lobe herniation or compression from a posterior communicating artery aneurysm. Thalamic (or diencephalic) lesions typically cause small, bilaterally reactive pupils. Midbrain injuries may lead to fixed, midsize pupils, whereas in pontine injuries the pupils are usually pinpoint. [12] Metabolic encephalopathies typically cause small, reactive pupils. Other signs associated with severe intracranial injuries include bradycardia and hypertension (Cushing reflex) caused by pressure to the floor of the medulla, and polyuria, which may indicate diabetes insipidus arising from pituitary damage, or cerebral salt wasting in patients with aneurysmal subarachnoid haemorrhage.

In all patients, the importance of sequential, repeated neurological examination to identify trends cannot be overestimated. Various scales are available to quantify sedation levels or risk of delirium; details of these can be found in Chapters 65 and 120 .

Lower extremities : Examine for swelling, peripheral perfusion and mottling. Note the presence of sequential compression devices and of peripheral oedema.

Other : Examination of the patient's back for pressure areas, sacral oedema.

Care should be taken to ensure that dressings are removed to allow inspection of wounds; ideally during scheduled changes, but this should not be delayed if there is a high index of suspicion. Vascular access sites should be inspected, and the duration of indwelling lines should be ascertained.

Special Circumstances

In this section, we describe particular scenarios that might require particular approaches or raise unique problems in PE. These are not exhaustive and the interested reader is directed to more detailed reference works in this field. [13]

The Burned Patient

Details of the initial assessment of burned patients are given in Chapter 103 . Day-to-day PE of patients with burn injury is often challenging; access may be limited by dressings, and sedation combined with frequent surgeries may confound neurological assessment.

In addition to the general approach described above, particular attention should be paid to:

Limb Perfusion and Compartment Syndromes

Dressings may preclude examination of the limbs, including the appreciation of distal pulses. It should be possible to at least assess capillary return in the tips of the fingers and toes. Signs of compartment syndrome may include tense fascial compartments or dark-coloured urine. Abdominal compartment syndrome is a recognised complication of burn injury and may arise from either circumferential abdominal burns or subsequent to high-volume fluid resuscitation. [14] Signs include hypotension, difficulty in ventilation and high intravesical pressures.

Head and Neck

Although ocular burns are relatively uncommon sequelae of facial burns, failure to recognise them promptly may lead to adverse outcomes. [15] Symptoms and signs of ocular burns may include pain, erythema, weeping, ulceration and oedema. Guidelines suggest that all patients with facial burns should have an ophthalmological assessment including a fluorescein stain examination. [16] Endotracheal tube fixation can be difficult, especially in patients with facial burns. Tube holders or tapes may aggravate injury or damage grafts. There are several suggested methods, including fixation to intermaxillary screws, interdental wire fixation and orthodontic brackets or arch bars. [17] The technique should be noted, and checks made for associated complications including infection at the site of implantation, or loosening of the fixture device. The site of a potential tracheostomy should be assessed and may indicate a need for early grafting. Signs suggestive of inhalational injury, such as facial singeing, and carbonaceous sputum should be looked for.

Other considerations during PE include assessment of line sites, both current ones for signs of infection, and potential new sites should a line change be required. Patients with cyanide toxicity may have a pink or cherry-red complexion. Examination of signs of associated injuries, particularly in the settings of blast or explosion should not be omitted.

The Septic Patient

As with any critically ill patient, a thorough PE, along the lines outlined earlier should be performed. In many patients presenting with sepsis or septic shock, this will reveal an immediately obvious focus of infection;

abdominal rigidity and tenderness may point to an intrabdominal source, or findings in the chest examination may indicate pneumonia for example. If a clear focus of infection is not readily apparent examination should include the following:

In patients with neurological signs, or decreased conscious level, examination for signs of meningitis, including neck stiffness, photophobia, or rash. Kernig's sign (pain or resistance to passive extension of the knee beyond 135 degrees) or Brudzinski's sign (reflexive flexion of the knees or hips following passive neck flexion) may be present.

Infective endocarditis should be considered when evaluating patients from a high-risk group such as those with signs of intravenous drug use or previous cardiac surgery, especially in the setting of embolic phenomena or intracranial haemorrhage. Conjunctival haemorrhages and Janeway lesions form part of the minor clinical criteria in the Modified Duke diagnostic guidelines. [18] Other cutaneous manifestations include Osler's nodes, petechiae, cutaneous infarcts and splinter haemorrhages. However, these manifestations are characteristic of chronic or subacute disease, which is now unusual in developed countries, where acute presentations are more common. In these cases, the most usual presenting finding is fever, which is non-specific. Splenomegaly is found in approximately 10% of cases. The lack of an audible cardiac murmur should not deter further investigations.

Inspection of the joints and limbs should be performed to identify effusions, swelling, erythema or abscesses. Likewise, examination of the skin including the perineum should be carried out. Bullae, discolouration, crepitus and pain out of proportion to the skin findings are suggestive of necrotising fasciitis. Erythroderma may indicate staphylococcal toxic shock syndrome and examination for a retained tampon may be appropriate. Desquamation of the palms and soles is commonly described in this condition but does not occur until one or two weeks after onset.

The onset of neurological signs in the limbs in a septic patient should raise the possibility of a spinal epidural abscess. These signs may be particularly difficult to elicit in sedated or obtunded patients and a high index of suspicion is required. Patients at particular risk include those with diabetes, intravenous drug users and those with bacteraemia or abscess formation at other sites. Regular clinical examination is required to identify changes that may warrant further investigations, such as magnetic resonance imaging (MRI).

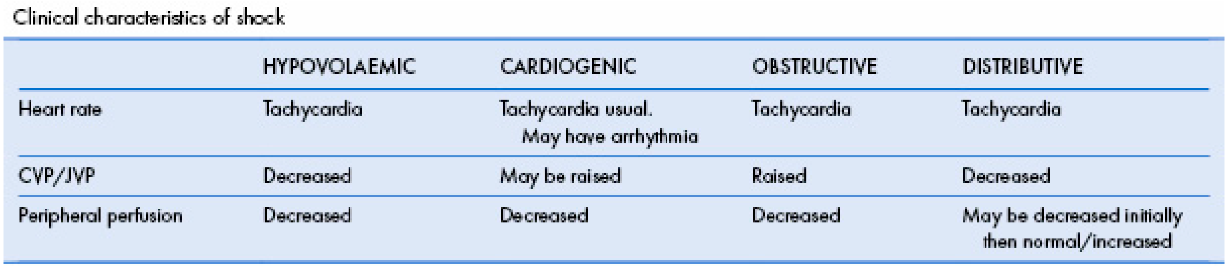
Catheter-related bloodstream infections (CRBSI) are common causes of sepsis in the ICU. While the commonest clinical sign associated with a CRBSI is fever, this is non-specific. At least one local sign at the catheter insertion point (pain, redness, non-purulent discharge, purulent discharge) has been noted to be significantly associated with the diagnosis of CRBSI. [19]

Other considerations in the PE of the septic patient include inspection of wounds (removing dressings if necessary) and drainage bags; examination of the mouth for gingivitis, dental caries and pharyngitis; and examination of the urine, stool and sputum.

The Shocked Patient

An overview of shock including characteristic clinical findings is given in Chapter 23 . Structured examination to ascertain the cause of the shocked state is essential and should proceed concurrently with resuscitation. Clinical findings associated with the general categories of shock are given in Table 9.3 ; however, it should be noted that this is a somewhat simplistic approach and that clinical findings can be influenced by the severity of the precipitating disease, the physiological reserve of the patient and the effects of medications.

Table 9.3



Clinical characteristics of shock

	HYPOVOLAEMIC	CARDIOGENIC	OBSTRUCTIVE	DISTRIBUTIVE
Heart rate	Tachycardia	Tachycardia usual. May have arrhythmia	Tachycardia	Tachycardia
CVP/JVP	Decreased	May be raised	Raised	Decreased
Peripheral perfusion	Decreased	Decreased	Decreased	May be decreased initially then normal/increased

Clinical findings which may be helpful in identifying the specific cause of the shocked state include:

- Differential blood pressures between the upper arms may indicate a dissecting aortic aneurysm as a cause of cardiogenic shock.
- A ‘millwheel murmur’ – described as ‘fluid splashing in a half-filled plastic bag’ [20] is characteristic of air embolism as a cause of obstructive shock.
- Priapism or lack of anal tone may indicate a spinal cord injury as a cause of distributive shock.
- Bruising of the flanks (Grey Turner sign) or peri umbilical bruising and oedema (Cullen’s sign) may be associated with retroperitoneal haemorrhage, although other intrabdominal pathologies can be responsible.
- Distended jugular veins, muffled heart sounds and hypotension (Beck’s triad) are suggestive of pericardial tamponade.
- Areas of hyperpigmentation may be seen in patients presenting with Addisonian crisis. The skin changes may be seen in the gums initially but can affect any part of the skin, particularly areas exposed to sun and to pressure. Pigmentation is seen only in primary adrenal insufficiency.
- Physical examination may also reveal iatrogenic causes of a shocked state; a kinked or obstructed thoracostomy tube, a dislodged central line or an inappropriately levelled arterial transducer, to give just a few examples.

The Fluid Responsive Patient

Predicting whether a critically ill patient will respond to fluid resuscitation is a crucial task in intensive care medicine but is notoriously difficult. The commonly used clinical signs; skin turgor, blood pressure, pulse rate and urine output are unreliable, as are static measurements such as central venous pressure or pulmonary artery occlusion pressure. [21]

Dynamic measurements, which assess the effect on stroke volume of heart-lung interactions during mechanical ventilation, or of a fluid bolus may have greater validity. There are a number of proprietary monitoring systems which use techniques such as pulse contour analysis to estimate the volume status of patients; echocardiography is also used for this purpose.

More information on these approaches is given in Chapters 24 and 25 . In this section, we will describe simple bedside techniques which use this approach.

Pulse pressure variation (PPV) describes the change in the difference between the systolic and diastolic blood pressure over the respiratory cycle. It can be manually determined as the ratio of the difference between the maximal and minimal values of pulse pressures over the mean of these two values but is more commonly automatically calculated by bedside monitors from the arterial waveform. It can also be subjectively assessed as the amount of ‘respiratory swing’. PPV has been shown to predict a response to a fluid challenge with a correlation coefficient of 0.78 and an area under the receiving operating characteristic curve (AUROC) of 0.94. [22] However these data were derived from studies in which patients had minimal spontaneous respiratory effort, no cardiac arrhythmias, and tidal volumes of greater than 7 mL/kg. If these circumstances do not apply, the accuracy of PPV may be reduced. Equally, high respiratory rates (heart rate/respiratory rate ratio <3.6), reduced lung compliance, high intra-abdominal pressures and right ventricular dysfunction all may impair the validity of the measurement. [23]

Passive leg raising (PLR) is performed by lowering a patient from a semi-recumbent position to supine, allowing the legs to rise to 45 degrees above the trunk. This has the effect of auto-transfusing approximately 300 mL of blood towards the right atrium, mimicking a fluid challenge. [24] PLR has been shown to predict a response to a fluid challenge with a correlation coefficient of 0.76 and an AUROC of 0.95. [25] The test has the advantage of being unaffected by spontaneous respiratory effort or arrhythmias, in contrast to PPV. However, the response to PLR should be assessed by a direct measurement of cardiac output which can record transient changes; using blood pressure or PPV to assess effect may be inadequate. It may be inaccurate in the setting of raised intrabdominal pressure, right heart failure and raised intra-thoracic pressure. If the patient is stimulated by the movement (coughing, or in pain) this may also confound the result.

Conclusion

A regular, thorough PE is an essential part of intensive care management. Critically ill patients present particular challenges to PE and adapting one's approach to the particular circumstances is required.

Severity scoring and outcome prediction

C Jake Barlow and David Pilcher

Application of Severity Scores

Why Use Them?

Many severity scoring systems have been developed in intensive care medicine. Most predict mortality in the general ICU population, including the Acute Physiology and Chronic Health Evaluation (APACHE) [2–5] series of scores, the Australian and New Zealand Risk of Death model (ANZROD), [6] the Intensive Care National Audit and Research Centre (ICNARC), Case Mix Programme (CMP) models, [7] the Simplified Acute Physiology Score (SAPS) [8–11] series, the Mortality Probability Model (MPM) [12–14] series and the Paediatric Index of Mortality (PIM) [15–17] series.

Other scores have been developed for specific populations, including patients requiring extra-corporeal membrane oxygenation (ECMO), specific diagnostic categories, such as trauma and sepsis, and specific organ systems.

You, a senior intensivist, arrive back at work following your holiday. On your desk, you find a letter from the Health Department. Your ICU is in the spotlight!

Looking through the document, the words ‘high mortality’, ‘outlier’, ‘Standardised Mortality Ratio’ and ‘confidence interval’ leap out at you.

> *You stretch your mind back, trying to recall the specifics of severity scores and mortality monitoring. Surely this can’t be right?*

Severity scores that predict mortality are often used for:

- **Quality of care evaluation and audit**
  Severity scoring systems allow appropriate interpretation and comparison of the mortality outcomes of patient cohorts and ICUs.
- **Resource allocation and management**
  Severity scoring systems can be used to compare predicted mortality to resource use [18] and length of stay, and potentially estimate efficiency. [19]
- **Comparison of groups in research trials**
  Scoring systems allow illness severity to be compared in different arms of a research trial.

Scoring systems are used by many well-established clinical quality registries, including the Australian and New Zealand Intensive Care Society (ANZICS), Centre for Outcomes and Resources Evaluation (CORE), ICNARC in the United Kingdom, The Japanese Intensive Care Patient Database (JIPAD), Epimed in Brazil and The Dutch National Intensive Care Evaluation registries.

Severity Scores, Mortality Prediction Models, Risk of Death and Scoring Systems: What is the Difference?

These terms are often used interchangeably but each is a distinct entity.

A score is an arbitrary number, where a high value typically represents a greater severity of illness and therefore chance of death. Such scores are created by weighting physiological variables and other factors, such as diagnosis or location prior to admission, to produce a total score. For example a patient with an APACHE II score of 35 is sicker than a patient with a score of 25, but neither number quantifies the actual chance of death.

Mortality prediction models (MPMs) use statistical techniques and more recently ‘machine learning’ methodologies to estimate the chance of death of a patient or cohort. A severity score is often a key component of MPMs.[20] The predicted mortality or ‘risk of death’ for a patient is the quantitative assessment of the likelihood of death. This is derived from an equation that may incorporate the severity score or its components, and also other factors, such as disease category, admission type or location prior to admission. Two patients with the same severity score may have a different predicted risk of death, depending on the impact of these other factors.[21]

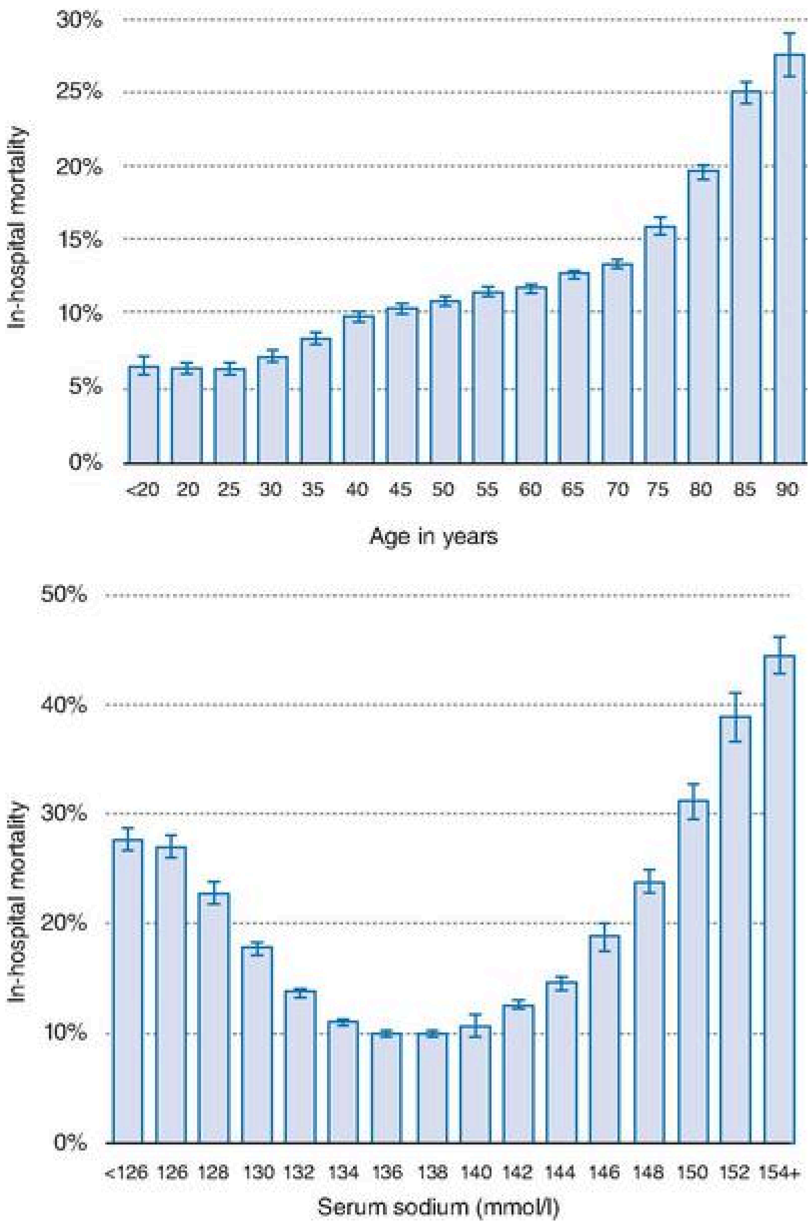
A scoring system refers to the combination of a severity score and a separate ‘equation’ to predict mortality risk. The APACHE scoring system produces both a score (incorporating age, chronic disease and physiological variables) and separately a predicted risk of death, produced by combining the same variables with additional information including ICU admission diagnosis, location and time in hospital prior to ICU admission and emergency surgical status.

Severity scoring systems should also be differentiated from ‘decision support tools’, which are used to inform a decision or intervention about an individual patient. Common decision support tools include early warning systems to detect patients with or at risk of deterioration in general wards. Some of these use MPMs as their basis to stratify management decisions.[22] This distinction is relevant because severity scoring systems, although effective at predicting outcomes at the population level, remain too imprecise to accurately quantify an individual patient’s risk and so cannot be applied at the bedside to aid clinical decision making.[22] Tools such as these are outside the scope of this chapter.

Principles of Mortality Prediction and Severity Scores

How Is a Score or Predicted Risk of Death Created?

The first step is to identify variables which have a relationship with mortality. For instance, elderly patients are more likely to die than the young, and many physiological variables have a ‘U’ shaped relationship with mortality (Fig. 10.1).



The pair of bar graphs shows the increased mortality at different ages and serum sodium levels. The top graph plots hospital mortality on the vertical axis and age in years on the horizontal axis. Mortality increases gradually with age, beginning at approximately 5 percent for ages less than 20 and peaking near 30 percent for ages 90. Age categories are displayed in intervals of five years from 20 to 90 years. The bottom graph plots hospital mortality on the vertical axis and serum sodium in millimoles per litre on the horizontal axis. Mortality rates form a U-shaped curve, starting at about 30 percent for sodium levels less than 126 millimoles per litre, decreasing to around 10 percent between 136 and 140 millimoles per litre, and rising again to over 45 percent for sodium levels at or above 154 millimoles per litre. Horizontal axis categories range from less than 126 to 154 plus, with increments of two millimoles per litre. Vertical gridlines mark 0, 5, 10, 15, 20, 25, and 30 percent in the top graph, and 0, 10, 20, 30, 40, and 50 percent in the bottom graph. Error bars are present above each bar to denote variability.

FIG. 10.1 In hospital mortality at different ages and serum sodium levels. The *top panel* shows the relationship between the in-hospital mortality and in years; the *bottom panel* shows the relationship between in-hospital mortality and day 1 serum sodium level for 551,365 ventilated patients admitted to 208 Australian and New Zealand Intensive Care Units (2013–2022). (From ANZICS Adult Patient Database.)

Secondly, an equation or algorithm is derived which connects the measured variable to the outcome. This can then be used to create a ‘score’ or to estimate the likelihood of death for any given combination of these variables, and in turn, be applied to future patients.

Key considerations when evaluating a variable are the strength of the relationship with mortality, the size of the dataset used, and practical aspects such as the burden of data collection. For example the SOFA[23], [24] score is relatively simple and can be ‘added up by hand’, whilst the predicted risk of death from APACHE IV,[5] the ICNARC model[7] and ANZROD[25] require a computer-based calculation.

One of the most common techniques used in developing severity scores is logistic regression,[26] which is ideal for binary outcomes (such as ‘alive or dead’). Recently, machine learning and artificial intelligence technologies have provided even more options for prediction modelling.[27] In addition, the predictive capacity of one variable may differ between individual patient groups. For instance, the GCS (Glasgow Coma Scale) is more strongly related to the outcome of patients with neurological injuries than those with elective cardiac surgery. Machine learning techniques can offer advantages due to their capacity to tailor predictive algorithms to specific combinations of variables.[28], [29] Whilst this may provide a more accurate prediction, it can come at the expense of increasing complexity, the opacity of the calculation method, the risk of overfitting and potential limitations to the generalisability of the model outside of its derivation dataset.

Evaluation of a Scoring System

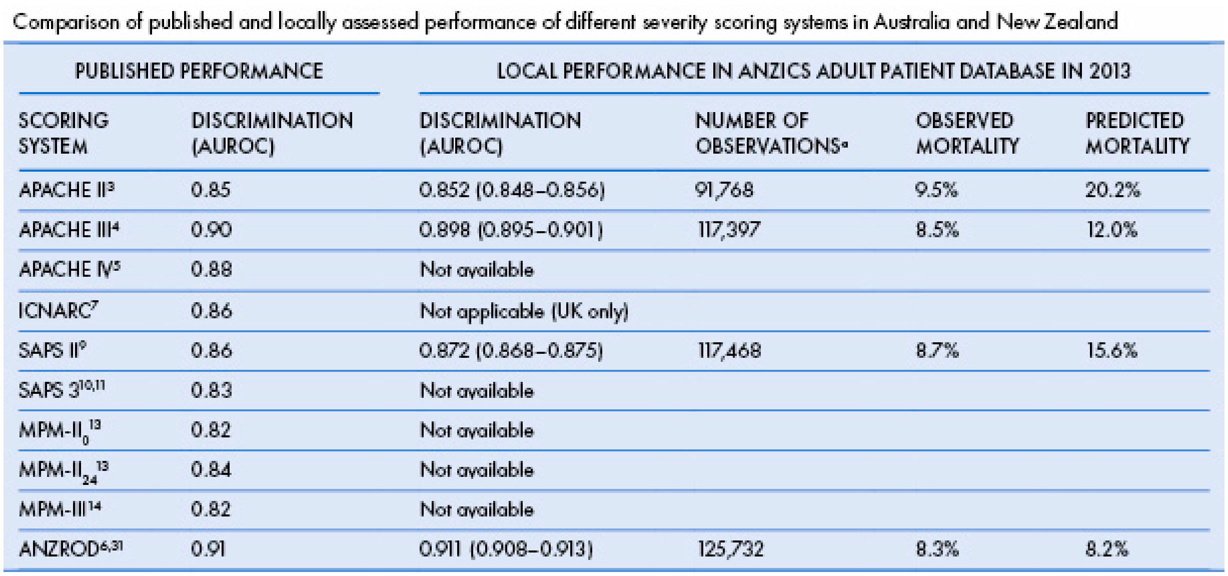
It is important to know how well a scoring system relates to observed mortality and how well it performs in specific patient cohorts to compare different groups of patients, ICUs and time periods. Models can be evaluated on three key components:

- Discrimination
- Calibration
- Validity

Discrimination

Discrimination evaluates how well a prediction model distinguishes those who will die from those who will survive.[30] Discrimination is commonly represented by the area under the receiver-operating characteristic curve (AUROC). Models where prediction performs no better than chance have an AUROC of 0.5, while those with excellent discrimination have an AUROC greater than 0.9. Although MPMs with a greater AUROC may be considered ‘better’, a highly discriminatory model may have limited use if its calibration is poor (see below). In datasets with very low event rates, other measures such as precision-recall curves may provide a more accurate assessment of model discrimination. A comparison of the AUROCs of common severity scoring systems can be seen in Table 10.1 .

Table 10.1



Comparison of published and locally assessed performance of different severity scoring systems in Australia and New Zealand

PUBLISHED PERFORMANCE		LOCAL PERFORMANCE IN ANZICS ADULT PATIENT DATABASE IN 2013			
SCORING SYSTEM	DISCRIMINATION (AUROC)	DISCRIMINATION (AUROC)	NUMBER OF OBSERVATIONS[a]	OBSERVED MORTALITY	PREDICTED MORTALITY
APACHE II[3]	0.85	0.852 (0.848–0.856)	91,768	9.5%	20.2%
APACHE III[4]	0.90	0.898 (0.895–0.901)	117,397	8.5%	12.0%
APACHE IV[5]	0.88	Not available			
ICNARC[7]	0.86	Not applicable (UK only)			
SAPS II[9]	0.86	0.872 (0.868–0.875)	117,468	8.7%	15.6%
SAPS 3[10,11]	0.83	Not available			
MPM-II$_0$[13]	0.82	Not available			
MPM-II$_{24}$[13]	0.84	Not available			
MPM-III[14]	0.82	Not available			
ANZROD[6,31]	0.91	0.911 (0.908–0.913)	125,732	8.3%	8.2%

[a] Number of observations based on application of specific exclusions for each scoring system to dataset.

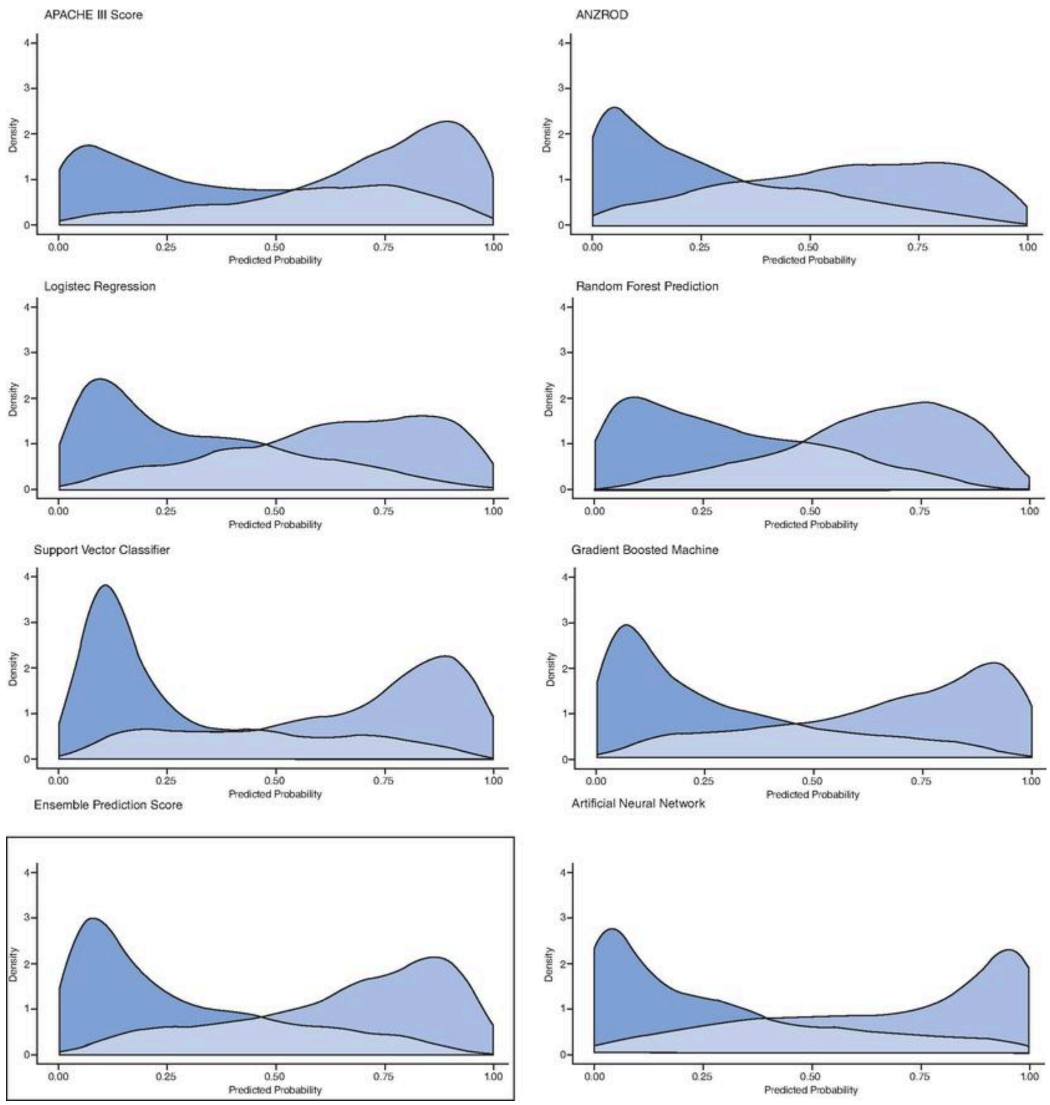
Calibration

Calibration describes how close the predicted values for mortality are to the real observed values. Application of a model to a different dataset than that used to produce it typically results in a loss of calibration. This loss may be minimised by controlling for case mix, geographic location and time period. Many scoring systems (APACHE II, SAPS I and II, MPM I and II) exclude cardiac surgery and have poor calibration if the scores are applied in this cohort compared to the use of specialised scores, [32] such as Euroscore [33–35] and the cardiac surgery score (CASUS). [36] Some scoring systems, such as

ANZROD and ICNARC, overcome this limitation by applying separate algorithms for specific cohorts, such as cardiac surgery.[6,37]

Calibration typically worsens over time, as observed mortality tends to fall as the quality of care improves, but predicted mortality remains the same as when the score was derived.[6,21] Mortality improvements may not be uniform across all patient groups, and the degree to which observed mortality falls below predicted may be different in specific patient subgroups. In addition, the emergence of COVID-19 which put unprecedented strain on ICUs in many parts of the world, inevitably affected patient outcomes and made the use of historical prediction models much more unpredictable over this period.[38] Consequently, MPMs require recalibration on a regular basis (Fig. 10.2).



The set of eight density plots is arranged in four rows and two columns. Each plot has the vertical axis labelled density and the horizontal axis labelled predicted probability, ranging from 0.00 to 1.00. Each plot compares two distributions represented as overlaid curves and shaded areas. The top left plot is titled Apache 3 score, and the top right is titled Anzrod. The second row contains logistic regression and random forest prediction. The third row contains a support vector classifier and a gradient boosted machine. The bottom row includes the ensemble prediction score on the left and the artificial neural network on the right. All plots exhibit varied curve shapes and peak distributions across the probability range, visually representing the calibration and spread of model predictions.

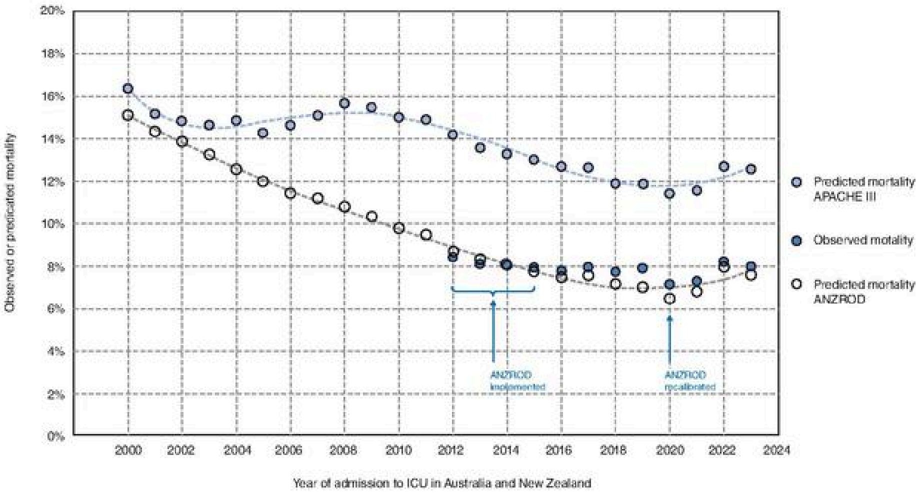
FIG. 10.2 Probability distribution curves of different statistical and machine learning models for prediction of in-hospital mortality derived from 39,566 patients admitted due to a cardiac arrest to 186 ICUs in Australia and New Zealand (2006–2016). Survivors are indicated in *green* and non-survivors are indicated in *red* . The ensemble model (*bottom left*) which combines multiple methods has the best performance characteristics. (Adapted with permission from Nanayakkara S, Fogarty S, Tremeer M, et al. Characterising risk of in-hospital mortality following cardiac arrest using machine learning: a retrospective international registry study. *PLoS Med* . 2018;15(11):e1002709.)

It is worth remembering that even when MPMs are recalibrated and the risk of death is ‘re-estimated’, a severity score remains unchanged. Patients with bacterial pneumonia, aged between 65 and 70, with APACHE II scores between 20 and 25, had a mortality of 27% in Australia and New Zealand in the early 2000s. Mortality fell to 23% between 2006 and 2010, and then to less than 18% over the next decade: these are the patients, with the same severity scores, but different mortality in different eras. Notably between 2020 and 2022, the mortality of this cohort rose again to 23% during the COVID-19 pandemic.

Calibration versus Discrimination

A model can be well calibrated even if its discrimination is poor, and vice versa. The Baux score (the sum of age and percentage total body surface area burnt) which is used as a predictor of burns mortality, is a well-known example of a score with strong discrimination (AUROC = 0.9) but poor calibration.[39], [40] Patients with higher Baux scores are much more likely to die than those who score lower. However, a 50-year-old man with 50% burns does not have 100% mortality. In Australia in 2012, it was 35%.[39]

APACHE III predicted mortality remains highly discriminatory in Australia and New Zealand even in 2019, but its calibration is much worse than the locally derived ANZROD (Fig. 10.3).



The graph plots observed and predicted mortality percentages on the vertical axis and year of admission to I C U in Australia and New Zealand on the horizontal axis, covering the years from 2000 to 2024. Three series are represented: Predicted mortality using Apache 3, Observed mortality, and Predicted mortality using Anzrod. Predicted mortality from Apache 3 remains between 14 and 17 percent across the timeline, while observed mortality steadily declines from above 15 percent in 2000 to around 8 percent by 2014, and fluctuates between 7 and 9 percent thereafter. Predicted mortality using Anzrod declines consistently from 2000 until around 2014, aligning more closely with observed mortality from 2014 onward. Two labelled arrows below the graph mark key points. One arrow labelled Anzrod implemented spans the years 2013 to 2015. Another arrow labelled Anzrod recalibrated points to the year 2020. The vertical axis ranges from 0 to 20 percent in increments of 2 percent. The horizontal axis is labelled in two-year intervals from 2000 to 2024. A legend at the right distinguishes the three lines by marker type and label.

FIG. 10.3 Receiver-operating characteristic (*top panel*) and calibration (*bottom panel*) curves showing the performance of ANZROD (*blue*) and APACHE III (*green*) mortality predictions in 183,937 patients admitted to 187 ICUs in Australia and New Zealand in 2019. Both have excellent discrimination (ANZROD 0.918 (95%CI: 0.916–0.921); APACHE III 0.897 (95%CI: 0.894–0.899) but ANZROD has better calibration with predicted mortality much closer to observed values. (From ANZICS Adult Patient Database.)

Validity

Validity describes how accurately a model reflects reality and is divided into internal and external validity. Internal validity describes how well the model represents the population in which it was developed. External validity describes how reliably the model performs in other populations. Validity is a function of discrimination, calibration and context.

Restricting the scope of the score reduces heterogeneity, may improve discrimination and calibration, but also limits generalisability. [11] An example is qSOFA, [41] which was developed to identify patients who are at greater risk of death from infection and thus need intervention or treatment. It is valid for use outside the ICU and in the ED [42] as a screening tool. However, qSOFA has to limited predictive capacity for identifying those at greater risk of death within the ICU, and so has little validity as a screening tool for sepsis within a critical care environment. [43]

Limitations of Scoring Systems

The application of severity scores is limited by the properties of the statistical methods used to generate them.

Applicability to Individual Patients

Severity scores predict the outcome of a cohort and are most accurate when the cohort comprises patients who are similar to each other. Models may become inaccurate when applied to an individual, so ICU illness severity scores are of limited benefit when making treatment decisions at the bedside. Although a patient with an APACHE II score of 8 is relatively well compared to a patient with a score of 25, the confidence interval for estimated mortality is too wide to accurately determine whether an individual will survive or die. [44]

Severity scoring systems are complex and patients may be incorrectly scored, with one study concluding more patients are scored incorrectly than correctly. [45] At a cohort level, a roughly equal distribution of errors may offset one another, but at an individual level, incorrect scoring may result in significant changes to predicted mortality.

Additionally, using an illness severity score to make individual treatment decisions may change the predictive ability of the score. If a life-sustaining treatment were withdrawn solely on the basis of a predicted mortality of >90%, this group would then likely have much higher mortality and the scoring system will be inherently less accurate! Thus individual mortality predictions are typically not recommended as ‘decision support tools’ but are more useful to interpret and compare the observed outcomes of cohorts of patients. [22]

Geographical Variation

Scoring systems developed in one region often require adjustment or modification to be applicable in other regions, even in those with superficially similar health care systems. [6,7,46] Several scoring systems have been developed using data pooled from ICUs in multiple countries. The global open source severity of illness score (GOSSIS) was derived from 380,280 patients from 366 ICUs in Australia, New Zealand and the United States. [47] SAPS 3 incorporates a ‘geography variable’ into the mortality prediction estimation for each region and is widely used in Europe and South America. [10,11] Several countries have local MPMs which have evolved from scoring systems derived elsewhere, such as ANZROD in Australian and New Zealand ICUs, [25] the ICNARC model in England and Wales [7] and JROD (Japan Risk of Death) in Japan. [46]

The challenges of creating and using scoring systems in low- and middle-income countries are well recognised. [48] Although few scoring systems have been developed in these regions, appropriate risk adjustment is as relevant to interpreting the outcomes of patients in these areas as it is in the rest of the world. [49] Increasingly, collaboration through groups such as the linking of global intensive care (LOGIC) provides an opportunity to learn from the experiences of clinicians in different countries and compare the practices and outcomes of intensive care patients worldwide. [37] , [50]

Using Severity Scores to Monitor ICU Outcomes

Comparisons of unadjusted death rates between ICUs lack context and can be misleading. One hospital might have twice the death rate, but the patients might also be twice as sick. Even with identical quality of care, patients who are more seriously ill die more often. Severity scores and mortality predictions allow us to adjust for this baseline risk.

Common methods include the standardised mortality ratio (SMR) for cross-sectional data comparing many ICUs, and control charts to continuously monitor outcomes over time using exponentially weighted moving averages (EWMA) and cumulative sum (CUSUM) charts.

Standardised Mortality Ratio

The SMR is the ratio of the total number of observed number of deaths compared to the total predicted number of deaths derived from the MPM.

$$\text{SMR} = \frac{\text{Observed deaths}}{\text{Predicted predicted}}$$

An SMR >1 indicates that the observed mortality exceeds the predicted mortality, an SMR <1 indicates the opposite.

Catches and Caveats in Interpreting the Standardised Mortality Ratio

The SMR relies on accurate measurement of observed mortality and accurate calculation of predicted mortality. Accurate interpretation is dependent on knowing which groups are included: readmission episodes to the ICU during the same hospitalisation, or patients with unknown outcomes are generally excluded. When reporting SMRs, some organisations either exclude patients transferred from an ICU or those transferred to another ICU. [17] SMRs for most adult ICUs consider in-hospital deaths. [2, 4, 6, 11, 51] However, it is common for paediatric ICUs to report and consider in-ICU deaths as the primary outcome. [17]

Observed mortality depends upon the quality of all care delivered both within and outside the ICU. Some deaths may be inevitable, others may be preventable. [52] Several scoring systems account for this by excluding those admitted for organ donation or palliative care [6] (where survival is not the aim of the ICU admission), or by providing a statistical adjustment to mortality prediction for those with treatment limitations. [14, 25] Accurate calculation of predicted mortality also relies on the quality of data acquisition and the specific characteristics and calibration of the prediction model used to estimate the predicted number of deaths.

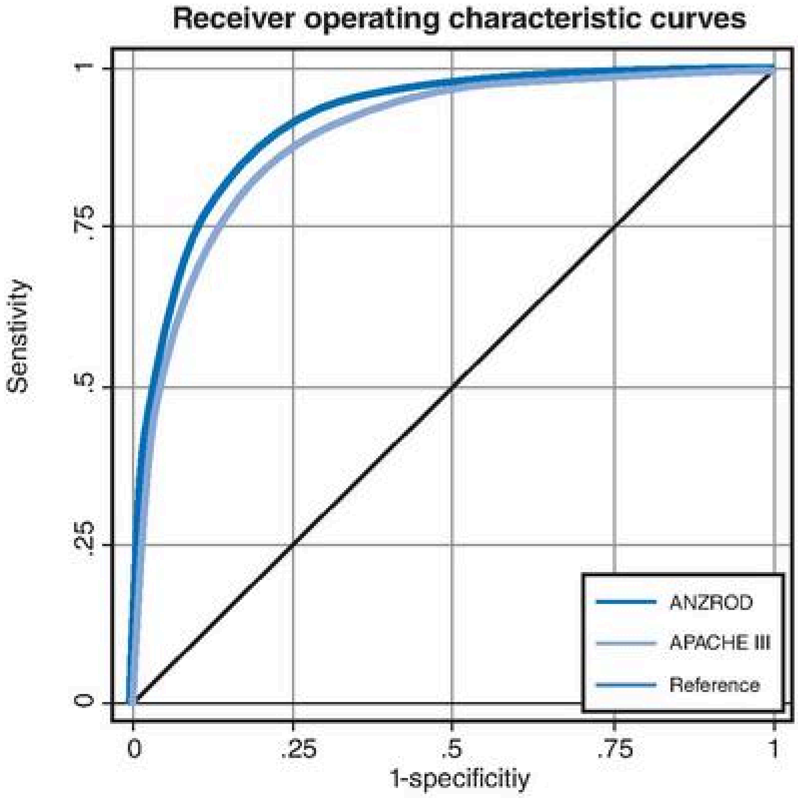
Anything which affects the calibration of the MPM will also affect the calculated SMR. The annual fall in APACHE III SMRs in Australia and New Zealand is partly due to improved quality of care and better mortality outcomes. However, it is also influenced by changes in data quality and the numbers and characteristics of contributing ICUs (Fig. 10.4).

Sitting down with the SMR report, you use the ‘Mohammed pyramid model’ of investigation to try and identify the cause. [1, 2]

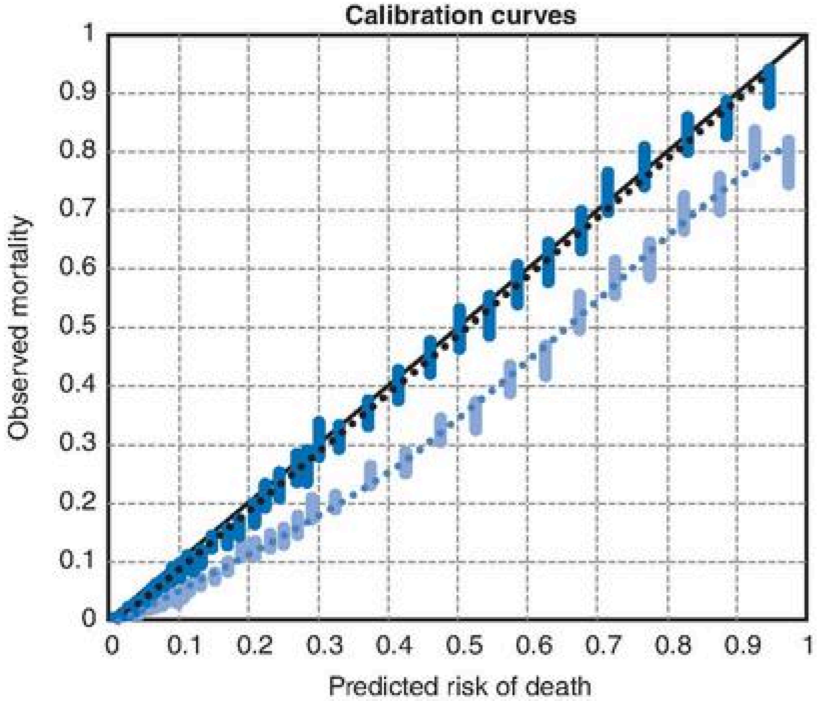
First, you examine coding and data quality, consistency and completeness. You ensure there are no implausible values, and that survivors and deaths are correctly coded. You concentrate on variables which may be systematically miscoded such as GCS.

Second, you evaluate the case mix. Are there patient groups where predicted mortality has been inaccurately estimated or where the prediction model systematically under-estimates true observed mortality? Are there groups of patients where there is a true elevation of mortality above predicted?

Third, you assess clinical factors. These include staffing, resources, access to ICU, processes of care, guideline availability and adherence and the clinicians themselves.



Receiver operating characteristic curves



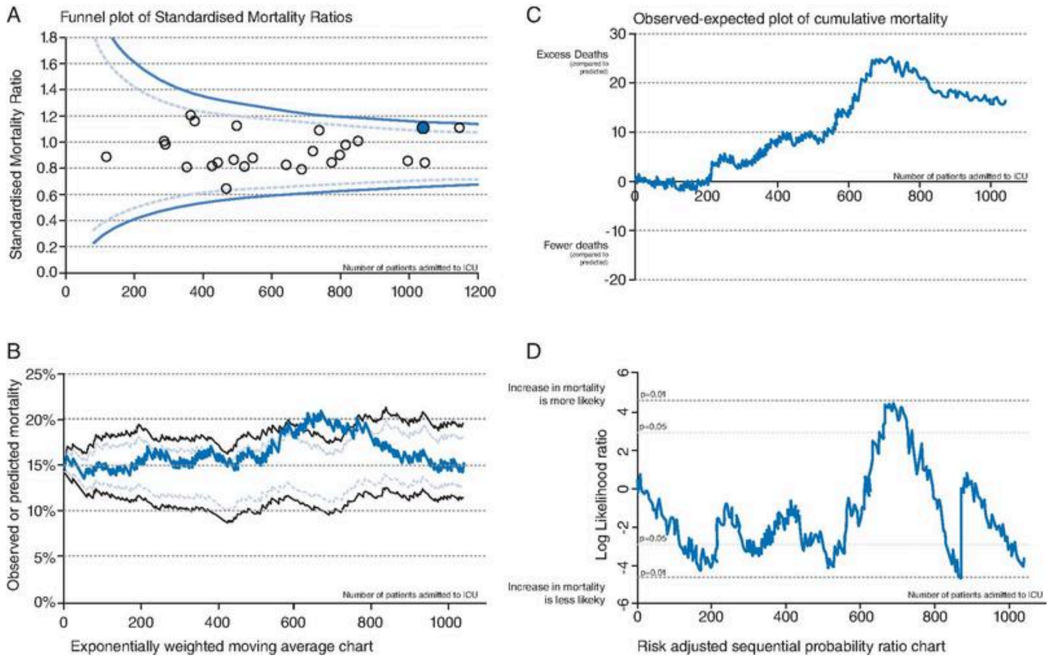
Calibration curves

The pair of evaluation graphs shows curves comparing the Anzrod and Apache 3 models. The top graph is labelled receiver operating characteristic curves. It plots sensitivity on the vertical axis and 1-specificity on the horizontal axis, both ranging from 0 to 1. Two curved lines represent model performance, one for Anzrod and one for Apache 3, comparing against a diagonal reference line from the bottom left to the top right corner. Both curves bend sharply upward before flattening near the top edge, with the Anzrod curve positioned above the Apache 3 curve. A legend in the lower right of the graph matches each line to its respective label. The bottom graph is labelled calibration curves and plots observed mortality on the vertical axis against predicted risk of death on the horizontal axis. Both axes range from 0 to 1. Two sets of data points and vertical bars are plotted, corresponding to the Anzrod and Apache 3 models. A diagonal reference line extends from the origin to the upper right, representing perfect calibration. The Anzrod data points closely follow the reference line, while the Apache 3 points deviate below it, particularly at higher predicted risks. The layout presents both discrimination and calibration comparisons between the two models.

FIG. 10.4 Change in observed mortality (*white*) and predicted risk of death derived from the APACHE III (*green*) and from ANZROD (*blue*) scoring systems, for 2,773,990 admissions to 219 ICUs in Australia and New Zealand between 2000 and 2023. In 2000, 85 ICUs contributed data, whereas 196 ICUs contributed data in 2023. The decline in observed mortality has been due to improvements in the quality of care but also changes in numbers and characteristics of contributing ICUs. The changes in predicted mortality are in part related to true changes in the characteristics of patients but also improvements in data quality. (From ANZICS Adult Patient Database.)

Graphing the Standardised Mortality Ratio and Identifying Potential Outliers

The most common graphical method used to report the SMR is a funnel plot (Fig. 10.5). Funnel plots graph the SMR for a group of ICUs over a period of time against the number of 'eligible cases' (typically number of ICU admissions or predicted number of deaths) on the x-axis.



The set of four graphs is arranged in a two-by-two layout, labelled A to D. Graph A in the top left is titled funnel plot of standardised mortality ratios. The vertical axis shows the standardised mortality ratio ranging from 0.0 to 1.8, and the horizontal axis shows a number of patients admitted to I C U ranging from 0 to 1200. Data points are distributed within tapering funnel-shaped boundaries, starting at 0.2, 1.8, and ending at approximately 0.6, 1.2. Graph B in the bottom left is titled exponentially weighted moving average chart. The vertical axis ranges from 0 percent to 25 percent, and the horizontal axis ranges from 0 to just above 1000 patient admissions. A central line is flanked by upper and lower control limits, showing variation over time. Graph C in the top right is titled observed-expected plot of cumulative mortality. The vertical axis ranges from negative 20 to 30 and the horizontal axis spans from 200 to 1100 patients. A single upward curving line starts near zero, climbs to a peak, and stabilizes. Text labels on the vertical axis mark zones of excess deaths and fewer deaths. Graph D in the bottom right is titled risk adjusted sequential probability ratio chart. The vertical axis ranges from negative 2 to positive 6 and the horizontal axis represents number of patients admitted to I C U. The plotted line rises and falls with several peaks and valleys. Horizontal reference lines at specific thresholds divide the graph into areas where an increase or decrease in mortality is more or less likely.

FIG. 10.5 Funnel plot and continuous outcome monitoring (control) charts. *Panel a (top left):* The panel shows a funnel plot of standardised mortality ratios (SMRs), with 95% (*blue dashes*) and 99% (*grey line*) confidence intervals drawn around the mean SMR of the group. *Panels a, b* and *c* show exactly the same data in three different ways. *Panel b (bottom left):* Exponentially weighted moving average of observed mortality (*in red*) plotted against 2 (*blue dashes*) and 3 (*grey lines*) standard deviations for the predicted mortality. *Panel c (top right)* : Observed minus expected plot of cumulative mortality, with more deaths than predicted as the *red line* climbs. *Panel d (bottom right)* : Risk-adjusted sequential probability ratio chart, showing the rising likelihood of an increase in mortality over predicted present as the *red line* climbs. *Explanation* : The ICU highlighted in *red* has an SMR which is ‘just within’ the acceptable control limits. Despite an overall acceptable SMR, during the middle of the monitoring period, mortality outcomes appear to deteriorate. (From ANZICS Adult Patient Database.)

When ICU admission numbers are small, random variation has to be considered. Small changes in observed numbers of deaths may cause large changes in the calculated SMR. The estimate of SMR becomes more robust as the number of observed and expected deaths increases.

Funnel plots also include confidence intervals, which indicate the expected random variation in SMR. The confidence intervals are also known as a control limits. The confidence interval indicates the precision of the SMR, with its width inversely related to the number of patients. An ICU with an SMR above the confidence intervals of the whole group is considered a potential outlier with more deaths than predicted and may indicate poor performance.[53] Variation within the confidence limits is likely due to random noise.[54]

Funnel plots of SMR can accommodate some degree of loss of calibration in the MPM because confidence intervals are often drawn around the 'average SMR' of the group rather than around an SMR of 1. Hence the group of hospitals shown becomes the determinant of the overall acceptable performance and range of SMRs.

There are several reasons why an SMR may lie outside of the confidence interval. It may be due to random variation (1% of SMRs may lie outside of the 99% confidence intervals), poor calibration of the prediction model, case-mix variation (important if mortality predictions are more accurate in one group than another) and coding errors (which can affect both observed mortality and the calculation of predicted risk of death). If a funnel plot has a 'shotgun' appearance with large numbers of hospitals outside the funnel confidence intervals (over-dispersion), this suggests the 'risk adjustment' is inadequate and the predicted mortality rates are inaccurate.

Despite these limitations, the funnel plot of SMRs is a useful screening tool to identify ICUs worthy of a 'closer look'.

Evaluating Performance Over Time for One ICU: Continuous Outcome Reporting

Display of outcomes over time for a single ICU often uses cumulative sum (CUSUM) or EWMA control chart techniques. Emerging trends can be identified early (possibly before a signal is seen on a funnel plot of SMRs), and clinical performance may be evaluated in near real time[55] (Fig. 10.5).

CUSUMs, EWMAs and VLADs

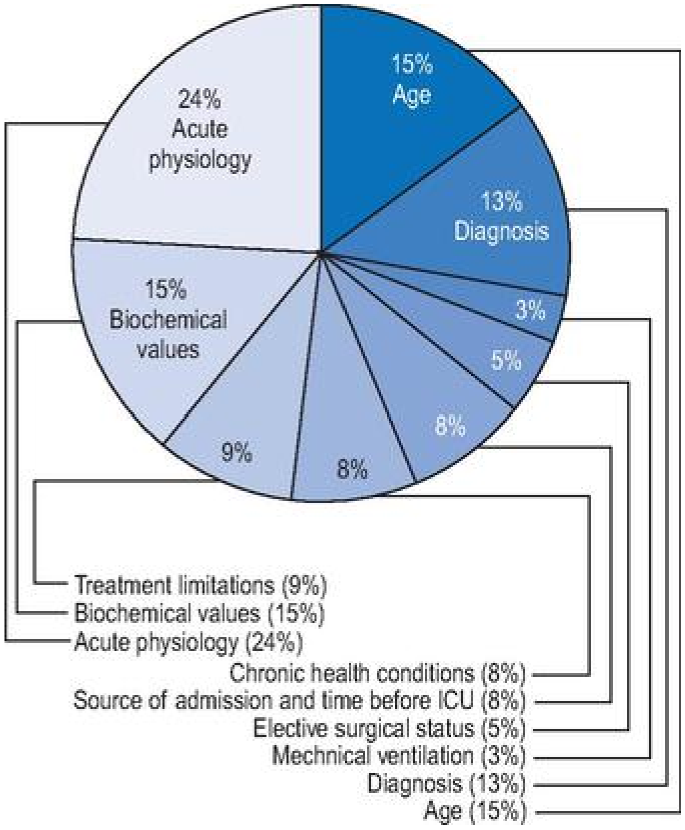
The basic CUSUM control chart displays a running total of the difference between observed and predicted outcomes.[55] The simplest forms are observed-expected charts. These may contain no control limits or confidence intervals to indicate when a trend should be considered significant. Risk-adjusted CUSUM and risk-adjusted sequential ratio probability charts are variants of these control charts, and sequentially assess whether an observed outcome rate is consistent with a specified baseline reference.[56]

EWMA charts are created by plotting the exponentially weighted mean of observed mortality alongside the predicted outcomes for the same patients, together with appropriate control limits. [55] They are able to detect small changes in mortality [55] because a small number of aberrant outcomes may reach a significance threshold. High sensitivity comes at the cost of a false positive rate which can be altered by changing the weighting used to create the chart. However, a common 'catch' is to overinterpret an uptick in observed mortality right at the end of a control chart. This is often due to the absence of 'long-stay survivors' who are yet to be included in the data.

Fig. 10.5 shows the same mortality data from one hospital displayed in three different ways with an observed-expected chart, risk-adjusted sequential ratio probability chart and an EWMA chart.

Common Features of Severity Scores and Mortality Prediction Models

All scoring systems in use rely on a limited number of patient factors to predict death (Fig. 10.6 , Table 10.2). These can be loosely categorised into markers of acute physiological disturbance, the primary pathological process driving admission, indicators of physiologic reserve (e.g. age and chronic disease state) and demographic factors. This section will discuss the properties of these factors with respect to severity scoring.



The pie chart is divided into ten labelled segments, each representing a contributing factor to mortality prediction in I C U patients. The largest segment is acute physiology at 24 percent, followed by age and biochemical values, each at 15 percent. Diagnosis accounts for 13 percent, treatment limitations for 9 percent, and chronic health conditions and source of admission, and time before I C U each contribute 8 percent. Elective surgical status and mechanical ventilation account for 5 percent and 3 percent, respectively. Each segment is annotated with a connector line and a corresponding label placed around the perimeter. The chart displays the proportional weighting of each factor within a predictive model.

FIG. 10.6 Relative contribution of variables to the ANZROD predicted risk of death. The figure shows the relative contributions of acute physiological disturbance *(‘acute physiology’, ‘biochemical values’),* primary pathological process (*‘diagnosis’),* physiological reserve (*‘age’, ‘chronic health conditions’*) and other factors (*‘source of admission and time before ICU’, elective surgical status’, ‘mechanical ventilation’, ‘treatment* limitations’) to predicted risk of death in the ANZROD model. Acute Physiological Disturbance

Since APACHE I, measures of physiological disturbance have been used to objectively estimate the severity of acute illness. [2] Initially, selection and weighting of variables was done by expert consensus, [2] but later scores used regression techniques to determine which variables should be included and how they should be weighted.

Commonly used markers of physiological disturbance are listed in Table 10.2 . Less commonly used markers include albumin, bilirubin, urea, haematocrit, glucose, lactate, platelet count, serum potassium and urine output.[2,5,7,11,14]

Sources of Error in the Acute Physiological Contribution to Mortality Prediction

Many markers of disease severity, such as hypotension, are also used as physiological targets for intervention. Early initiation of critical care interventions prior to recording the severity of illness scores may cause a patient to be assigned a score that does not reflect the severity of their initial physiological derangement. Delayed initiation of interventions may have the opposite effect. This error is greatest when physiological parameters being used to estimate risk on admission are measured after treatment has been initiated.[57] Variables most at risk for this bias are heart rate, blood pressure, respiratory rate, blood glucose, pH and PaO_2.[57] Continuous variables (e.g. heart rate) are more prone to measurement bias than binary ones (e.g. presence of NYHA III/IV heart failure).

Several methods are employed to reduce the error created by the effect of medical intervention. Using ICU admission data, which is earlier in the disease course and therefore less affected by it, is the approach taken by the MPM-II$_0$ and SAPS 3 score.[11,14] However, this strategy may also increase the proportion of missing values and reduce explanatory power. This can be avoided by using data from a later time point, which is typically more complete, and is the approach taken by the PIM 3 scoring system.[17] Other methods include substituting default (normal) values for missing data and omitting cases with unknown outcomes. Both of these methods significantly bias the calculated severity score.[58]

An alternative approach (used by APACHE, ANZROD and ICNARC) is to use the ‘worst’ value in the first 24 hours[4,22,58] following admission. This decreases the proportion of missing values whilst allowing evaluation of care occurring after this period. However, this approach may disguise poorly performing units, as the higher observed mortality will be attributed to increased physiological derangement which was a result of poor care in the first twenty-four hours of ICU stay.[59]

An additional factor to consider is ‘short-stay’ patients. Short ICU stays make up a significant proportion of the ICU workload, with 30% of deaths and discharges occurring in the first 24 hours of ICU admissions.[58] This provides little time to institute and see impact of ICU interventions, such that ‘short-stay’ patients may have an SMR close to one irrespective of the quality of care provided.[58] These are typically either very high-mortality patients who die shortly after admission or very low-risk elective surgical patients who are rapidly discharged from the ICU.

Primary Disease Process

The cause of admission is an important factor[4] as the prognosis of a particular physiological derangement will depend on the underlying pathology. For example a patient presenting with severe diabetic ketoacidosis will have comparatively low mortality compared to a patient with similarly deranged physiology due to sepsis.

It is therefore important to account for the primary disease process. The number of diagnostic categories used by different scoring systems varies widely: MPM III uses only 6,[14] SAPS 3 uses 39,[11] APACHE II uses 50,[3] ANZROD uses 177,[6] while ICNARC uses 709.[7]

Physiological Reserve

Physiological reserve is a broad term which encompasses a patient’s capacity to respond to a physiological insult without significant decompensation. Several factors are commonly measured to provide an index of physiologic reserve.

Age is both routinely measured and a good predictor of outcome. It is included in all common scoring systems.[2–4,7,11,14,25] However, the predictive relationship is broad and not absolutely linear (Fig. 10.1). Severe chronic organ insufficiency or immunocompromise is also included in several scoring systems.[3,4,9] Frailty has become increasingly recognised as an independent predictor of both short and long-term survival outcomes,[60,61] but has yet to be commonly incorporated into routine illness severity scoring systems. This is in part because the performance of the original score is so high that the inclusion of frailty often offers little additional improvement in discrimination but increases the burden of data collection.

Acute physiological derangement is a strong predictor of hospital mortality on admission and early in the ICU stay. However, with increasing ICU stay (in particular greater than around 10 days), antecedent characteristics including frailty become more predictive,[62–64] whilst the cause for ICU admission becomes less predictive.

Ethnicity

The significant health disparities between ethnic groups, particularly indigenous populations, are well recognised.[65,66] Proposed mechanisms include inequitable access to healthcare, increased comorbidities, socioeconomic factors, provision of a lower quality of care and influence of cultural factors. For example indigenous patients admitted to ICUs in Australia are significantly younger, more comorbid, suffer greater socioeconomic deprivation and are more likely to be admitted due to emergencies or exacerbations of underlying chronic disease.[65–68] Hospital and ICU mortality rates are similar in indigenous and non-indigenous populations; however, long-term survival following ICU admission is lower in indigenous groups.[66,69]

Ethnicity or race can potentially be included in MPMs, but this can be problematic. Offering a limited number of categories that are specific to the context of the tool may introduce bias by grouping ethnicities that are biologically or socioeconomically heterogeneous. Using a model which has been developed on data with pre-existing social and health inequities, can in itself lead to the creation of a severity score which perpetuates bias in health care provision. The importance of accounting for deprivation status when examining indigenous healthcare outcomes is well-recognised, although is not performed by any existing severity scoring system.[65,69]

Typically, severity scoring models demonstrate equal discrimination against all ethnic groups, although one US study demonstrated that

APACHE IVa and SOFA both over-predicted mortality in Black and Hispanic groups.[70] This reinforces that using severity scoring systems to make decisions about individual patient care, as occurred with guidelines for the allocation of limited ICU resources during the COVID-19 pandemic,[71,72] is highly fraught, may exacerbate race-based health disparities and is not recommended. This effect also impacts benchmarking, as units with a higher proportion of patients with an over-predicted mortality demonstrate a spuriously low SMR.

Location and Emergency Status

The location from which a patient is admitted may provide an indirect measure of disease severity by the level of care required by patients in that location.[4,56] Consequently, patient location is included as a covariate in some scores. SAPS 3 has three locations: emergency, another ICU or 'other'[10,11]; whilst the ICNARC model has six: elective surgery, emergency surgery, ward, ICU transfer, emergency or home.[7] Although the predictive power of location may be low, and its removal has almost no significant effects on model calibration and discrimination,[11] it is easily measured. In contrast, elective or emergency status can often have a large effect.[6]

Severity Scoring Systems in Common Use

APACHE I-IV

The prototype Acute Physiology and Chronic Health Evaluation (APACHE) score was derived in 1981 by Knaus, to allow evaluation of case mix in trials, compare outcomes, evaluate the efficacy of new therapies and evaluate resource use in ICUs.[2] The model was developed using data from 805 patients admitted to a university hospital ICU and a community hospital ICU within the United States. Cardiac surgery was excluded, and the values and weightings of each variable were decided by expert consensus of five physicians. [2] APACHE I has been superseded by later versions and is the only iteration not in current use.

A revised version (APACHE II) was released in 1985. [3] Infrequently measured physiologic variables were removed, as were variables that demonstrated poor predictive power. APACHE II was developed and validated using data from 5030 admissions to 13 different US ICUs. Weightings were still determined by expert consensus rather than regression modelling. The final APACHE II score is a sum of three components: the acute physiology score (from the worst values in the first 24 hours of ICU admission), a chronic health score and a score based on age. APACHE II has been the most commonly used and reported scoring system. Modern mortality outcomes are much lower than the original mortality predictions derived from the score components and admission diagnosis, reflecting the drift in calibration that occurs with improving quality of care.

APACHE III was released in 1991. [4] The derivation dataset was expanded, using 17,440 admissions from 40 US ICUs. APACHE III abandoned expert consensus for weighting predictive variables, moving to multivariable regression. A later update included cardiac surgical patients, making it the first APACHE score to do so. APACHE III was an improvement over APACHE II with better discrimination (AUROC 0.9, compared to 0.85) and calibration. Several updates to APACHE III have been released, using alphabetical designators (e.g. the 10th update is APACHE III-j which is publicly available).

The APACHE IV iteration was derived in 2006 from 110,558 admissions from 104 ICUs in 40 different US hospitals. [5] APACHE IV was developed due to poor calibration of APACHE III in modern patient populations. It takes into account sedative effects on the ability to score the GCS and has a more extensive admission diagnosis list. It is worth noting that although the APACHE III and IV scores are essentially interchangeable, the derived APACHE IV predicted risk of death has much better discrimination and calibration than its predecessor.

SAPS I-III

The Simplified Acute Physiology Score (SAPS) was developed in France in 1984 and was based almost entirely on physiological variables.[8] Like APACHE I, the variables and their weightings were determined by author consensus. SAPS I was primarily designed to overcome the complexity of APACHE I and was significantly easier to complete. SAPS I demonstrated equivalent discrimination to APACHE I in the derivation cohort of 679 patients. Each range of scores corresponded to a particular mortality rate.

SAPS II was an expanded version of SAPS I and was released in 1993.[9] Logistic regression was used to select variables for inclusion, decide on groupings for each variable and convert the severity score to a mortality prediction. SAPS II was an international effort, with data used from 13,152 patients from 10 nations across Europe and North America. Burns, coronary and cardiac surgical patients were excluded. Discrimination was greatly improved over SAPS I and was equivalent to APACHE III and MPM II, whilst still being quick to use.

SAPS 3 was published in 2005 and was derived from a database of 19,577 admissions to 307 ICUs across Europe; North, Central and South America; the Mediterranean and Australasia.[10,11] The equation is customised for each geographic area. The majority of the predictive power for SAPS 3 is from patient characteristics known prior to admission, whilst the circumstances surrounding admission and the acute physiological component contribute 22.5 and 27.5% respectively.[4,7,11] Though SAPS 3 has poorer explanatory power than APACHE IV, it has been applied to a greater proportion of the world than any other scoring system.

MPM I-III

The MPM was an evidence-based response to APACHE I and used data derived from a single US institution to compute the risk of death using a logistic regression equation.[12]

MPM II was released in 2005 and consisted of two versions: MPM-II $_0$ (assessed at ICU admission) and MPM-II $_{24}$ (assessed at 24 hours).[13] MPM-II $_0$ and MPM-II $_{24}$ have similar discriminatory power to SAPS II, with AUROCs of 0.82 and 0.84 respectively.

MPM III was introduced in 2007 in response to the falling calibration of MPM II.[14] The score was developed on a new dataset using the same variables, with the addition of whether the patient had a ‘do not resuscitate’ order at the time of admission. The subsequent analysis achieved significantly better calibration than the previous iteration, with an AUROC of 0.82.

The MPM systems have a low burden of data collection as variables are binary and all data is recorded at the time of admission. This simplicity is counter-balanced by poorer discrimination compared to other scoring systems.

The ICNARC Model

The Intensive Care National Audit and Research Centre (ICNARC) model[7] used in the United Kingdom, was originally published in 2007, and derived from data which was initially collected by ICNARC for the derivation of APACHE II, APACHE III, SAPS II and MPM II scores. It uses several of the same physiological parameters as the other scores but incorporates an expanded list of diagnostic criteria.

The first ICNARC model included data from 216,626 patients from 163 ICUs. The model is recalibrated regularly using data from the CMP to maintain accuracy within the derivation cohort. However, like APACHE it is based entirely on a national cohort and may not be suitable for use outside the United Kingdom.

ANZROD

The Australian and New Zealand Risk of Death (ANZROD) model was developed by the ANZICS CORE to replace APACHE III-j.[6] Data from 450,000 ICU admissions to 155 ICUs submitted to the ANZICS Adult Patient Database between 2004 and 2009 were used to develop the initial model, which was then recalibrated and introduced in 2015. An updated version was implemented in January 2020 with individual equations for each of the 122 diagnoses[31] (Fig. 10.3). Patients admitted for palliative care, organ donation or younger than 16 are excluded, but unlike many other models, burns and cardiac surgery are included. The model demonstrated better calibration and discrimination than APACHE III-j in Australasian hospitals (Fig. 10.4).

SOFA

The Sepsis Organ Failure Assessment (SOFA, later renamed Sequential Organ Failure Score) is an organ failure score. Organ failure scores can be used to predict mortality based on the number and severity of organ system failures. This is slightly different from the more general severity scores, which predict mortality from a variety of different explanatory variables.

The SOFA score was originally constructed to provide a simple, objective and reliable score for daily assessment of organ dysfunction in sepsis trials.[24] It scores the function of six organ systems (brain, cardiovascular, coagulation, renal, hepatic and respiratory) from 0 (normal) to 4 (extremely abnormal), with parameter intervals defined by expert consensus. These parameter intervals also include the effects of treatment, including mechanical ventilation, vasoactive supports and sedation. The final score is calculated daily using the worst values for each system.

The initial role of SOFA was not to predict mortality, but to quantify the sequence of events that occur in the critically ill patient.[24] SOFA has since been evaluated as a mortality prediction tool, and several derivative scores have been described for this purpose.[23], [73–75] These include the mean SOFA score (sum of all SOFA scores divided by the length of stay), the highest score and Δ-SOFA (defined differently in different trials, but in principle evaluating the difference between two scores [73], [74]). These derivative scores demonstrate strong discrimination. However, calibration was not assessed in all instances[75] and the use of SOFA as a replacement for existing severity scores is not warranted.

PIM 1-3

The Paediatric Index of Mortality (PIM) is a series of severity scores covering patients less than 16 years of age, who are typically excluded from other severity scoring systems. PIM1 was published in 1997, using data from seven Australian and one UK PICU. [15] Two further iterations have been released, [16], [17] with the latest version (PIM3) released in 2013. PIM3 was developed from 53,112 consecutive admissions to PICU (Paediatric Intensive Care Unit) in the UK, Ireland, Australia and New Zealand, and uses several physiological and admission variables. The PIM3 model includes all individuals under 16 admitted to a PICU, excluding those who were transferred to another ICU. The model demonstrates strong discrimination (AUC 0.88) across a range of predicted mortalities.

The PIM series is not the only paediatric-specific scoring systems, others include the Paediatric Risk of Mortality (PRISM) series of scores, [76], [77] and organ failure scores such as the Paediatric Logistic Organ Dysfunction Score (PELODS) series. [78], [79]

Scores for Specific Populations

Sepsis: qSOFA

The quick-SOFA (qSOFA) score was developed in 2016 as a bedside screening tool for patients with suspected infection and at risk of death. The score used three criteria, with one point given for low blood pressure (SBP ≤100), respiratory rate (>22 per minute) or altered mentation (GCS <15), to a maximum of three. [40] qSOFA showed better discrimination than either SIRS (Systemic Inflammatory Response Syndrome) and SOFA with respect to in-hospital mortality outside of the ICU (AUROC 0.81 compared to 0.76 and 0.79 respectively) but is a poor predictor of mortality within the ICU. [42]

Trauma: ISS

The Injury Severity Score (ISS) is an anatomically based scoring system for trauma patients, released in 1974. [80] The ISS is based on the Abbreviated Injury Scale (AIS), which classifies the severity of injury to six body regions (head and neck, face, chest, abdomen and pelvic contents, extremities or pelvic girdle and external). Injuries are graded from 1 (minor) to 6 (currently untreatable). [81] The ISS is then calculated from the sum of squares of the highest score in the three most severely injured regions.

Unlike physiological scores, which typically use data obtained close to the height of acuity, all injuries in ISS are relevant irrespective of the time at which they were detected. Therefore injuries identified in tertiary surveys, trauma follow-up and post-mortem examination, are included. The ISS also has weaker discrimination as it ignores chronic disease.

Others include the Trauma Score [82] and Revised Trauma Score, [83] which are based on age and physiological variables; and the Trauma and Injury Severity Score (TRISS) series, which combines both the Trauma Score and the ISS to give a combined anatomical and physiological scoring system. [84], [85] However, their performance in patients admitted to the ICU may be no better than generic ICU-based scoring systems. [86]

ECMO

Survival After Veno-Arterial ECMO (SAVE), [87] Respiratory ECMO Survival Prediction (RESP) [88] and ECMO Predictive Algorithm (PAL) [29] scores have been developed to predict mortality in patients who are already on ECMO. They perform better than generic ICU scores which often incorporate variables recorded after the institution of ECMO. These scores are valid to compare the outcomes of patients already receiving ECMO, not for determining selection for ECMO treatment.

Trials

Simon Finfer, Lennie P.G. Derde, Naomi E. Hammond and Anthony Delaney

Introduction

Evidence-based medicine is the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research. Clinical expertise is reflected […] in the more thoughtful identification, and compassionate use of individual patients' predicaments, rights and preferences in making clinical decisions.[1]

The most reliable evidence, and thus the best evidence for guiding clinical practice, will generally come from adequately powered and properly conducted randomised clinical trials (RCTs). It is commonly the case, however, that there are no RCTs that adequately address a particular question, so clinicians may have to assess the results of other studies, such as cohort studies, case-control studies and systematic reviews to supplement their clinical expertise. It is important that clinicians are familiar with the underlying principles and potential sources of bias in each of these study designs, so they can incorporate evidence from reliable studies into their clinical practice and treat with appropriate caution those studies whose design makes it likely that they will produce unreliable or misleading results.

Randomised clinical trials

Broadly speaking the result of any clinical trial may be influenced by three factors: a true treatment effect, the effects of bias or confounding, and the play of chance. RCTs, when properly designed, conducted and analysed, offer the optimal conditions to minimise bias and confounding, and to define the role that chance may have played in the results. As such, they represent the best study design to delineate true treatment effects under most circumstances. However, it is imperative that RCTs are designed, conducted, analysed and reported correctly. Studies that have not adhered to the principles outlined below may produce results that do not provide a true estimate of treatment effects.

The Question to Be Addressed

Every trial should seek to answer one, or several in the case of platform trials, focused clinical questions that can be clearly articulated at the outset. For example, 'we sought to assess the effect of different fluids on outcomes of intensive care patients', is better expressed as the following focused clinical question: 'we sought to address the hypothesis that when 4% albumin is compared with 0.9% sodium chloride (normal saline) for intravascular fluid resuscitation in adult patients in the intensive care unit (ICU), there is no difference in the rate of death from any cause at 28 days'.[2] The focused clinical question defines the interventions to be compared, the population to be studied and the primary outcome to be considered. This approach can be formalised using the PICO system: PICO stands for patient, intervention, comparison and outcome. In the example above:

- Patient = adult ICU patient
- Intervention = albumin
- Comparison = saline
- Outcome = 28-day all-cause mortality.

The question that a trial is designed to address will vary somewhat depending on the stage of development of the proposed treatment. After development and testing in animal models, the testing of pharmaceutical agents in humans is generally conducted in three phases. Sometimes a fourth phase is added:

Phase I trial : testing in healthy volunteers.
Phase II trial : first testing in a population of patients with disease to be modified, usually small trials focused on establishing safety and evidence of efficacy using surrogate outcome measures.
Phase III : large-scale trial in patients that has sufficient statistical power to determine the effect of the treatment on the primary outcome of interest (often survival or risk of death).
Phase IV : post-marketing trials to confirm safety once the agent is introduced into clinical practice.

Trials may be designed to answer two quite different questions about the same treatment, and the design will be quite different depending on the questions to be answered. An 'efficacy trial' seeks to determine whether a treatment will work under optimal conditions, whereas an 'effectiveness' trial seeks to determine the effects of the intervention when applied in normal clinical practice. A comparison of the features of efficacy and effectiveness trials is given in Table 11.1 from Hébert and colleagues. [3]

Table 11.1

[a] Data monitoring refers to the review of source documents and adjudication/verification of outcomes.

RCT , Randomised clinical trials.

Adapted from Hébert PC, Cook DJ, Wells G, et al. The design of randomised clinical trials in critically ill patients. *Chest.* 2002;121(4):1290–1300.

Population and Sample Size

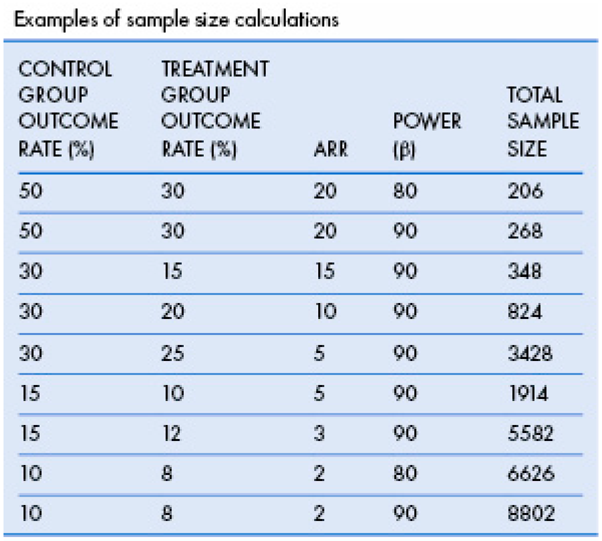
The population to be studied will be defined by the study question. Efficacy trials may have a very narrowly defined population, with strict eligibility criteria and many exclusion criteria. Effectiveness trials are likely to have more broad inclusion criteria and few exclusion criteria. Adaptive trials may modify the population recruited during their conduct stopping recruitment of patients who appear to be harmed by the treatment and/or focusing on subgroups of patients in whom the treatment appears to offer greatest benefit. Regardless of the design, the population to be studied should be well described. This will allow readers to assess the scientific merit of the study and allow clinicians to judge whether the results of the study could apply to their patients; to assess the ‘generalisability’ of the results. Trials that include only a very narrowly defined population may also face difficulties in recruiting sufficient participants to reach a definitive conclusion.

How large do trials need to be to reach a definitive conclusion? In a parallel group trial, with a dichotomous outcome (e.g. alive or dead), the number of patients required to answer a question depends on four factors:

1. The percentage of patients expected to have the outcome in the control group – the control group outcome rate.
2. The expected change (usually reduction) that may result from the treatment being tested – the treatment effect.
3. The level of probability to be accepted to indicate that the difference did not occur by chance (i.e. the probability level at which a treatment effect will be deemed to be real) – significance level or α (almost always 0.05) in a frequentist trial or the calculated posterior probability when using a Bayesian analysis.
4. The desired percentage chance of detecting a clinically important treatment effect, if one truly exists (power: usually 80% or 90%).

In the past, trials addressing issues of importance in intensive care medicine were commonly too small to detect clinically important treatment effects, [4] but fortunately this is now changing. [2,5] The conduct of underpowered trials has almost certainly given rise to a significant number of false-negative results (type II errors) leading to potentially beneficial treatments being discarded. Occasionally, small trials may produce false positive results (type I errors) when a large number of primary outcome events occur in one group due to the play of chance. To avoid these errors, clinical trials have to include a surprisingly large number of participants. Examples of sample size calculations for a frequentist trial based on different baseline incidences, different treatment effects and different statistical power are given in Table 11.2 .

Table 11.2



Examples of sample size calculations

CONTROL GROUP OUTCOME RATE (%)	TREATMENT GROUP OUTCOME RATE (%)	ARR	POWER (β)	TOTAL SAMPLE SIZE
50	30	20	80	206
50	30	20	90	268
30	15	15	90	348
30	20	10	90	824
30	25	5	90	3428
15	10	5	90	1914
15	12	3	90	5582
10	8	2	80	6626
10	8	2	90	8802

ARR, Absolute risk reduction.

All calculations performed with STATA 8.2, assuming a two-sided $\alpha = 0.05$.

Randomisation and Allocation Concealment

The commonest unit of randomisation in a clinical trial is the individual patient, that is, each patient included in the trial has an equal chance of being assigned to each treatment being studied. In cluster randomised trials patients are randomised in clusters and the unit of randomisation may be a hospital, wards or units within a hospital. [6] Cluster randomisation has important implications for the design and analysis of the trial and increases the sample size needed.

Regardless of the unit of randomisation, two components of the randomisation procedure are critically important. The first is the generation of a truly random allocation sequence; modern computer programs make this relatively straightforward. The second is the concealment of this allocation sequence from the investigators so that the investigators and participants are unaware of the treatment allocation (group) prior to each participant or cluster entering the study.

There are a number of benefits to using a random process to determine treatment allocation. First, it eliminates the possibility of bias in treatment assignment (selection bias). For this to be ensured, both a truly random sequence of allocation must be produced, and this sequence must not be known to the investigators prior to each participant or cluster entering the trial. Second, it reduces the chance that the trial results are affected by confounding. A characteristic (such as advanced age, gender and disease severity) that is associated with the outcome is known as a confounding factor. Randomisation of a sufficient number of participants ensures that both known confounders (e.g. age and severity of illness) and unknown confounders (e.g. genetic polymorphisms) are evenly distributed between the two treatment groups. The play of chance may still result in an uneven distribution of known or unknown confounding factors between the groups, and this is particularly likely in trials with fewer than 200 participants. [7] The third benefit of randomisation is that it allows the use of the probability theory to quantify the role that chance could have played when differences are found between groups. [8] Finally, randomisation with allocation concealment facilitates blinding, which is another important component in minimising bias in clinical trials. [9]

The generation of the allocation sequence must be truly random. There are a number of approaches to generating a truly random allocation sequence, most commonly using a computer-generated sequence of random numbers. More complicated processes where randomisation is performed in blocks or is stratified to ensure that patients from each hospital in a multi-centre trial or those with certain baseline characteristics are equally distributed between treatment groups, also can be used. Allocation methods based upon predictable sequences, such as medical record numbers or days of the week, do not constitute true randomisation and should be avoided. These methods allow researchers to predict to which group a participant will be allocated prior to them entering the trial, which introduces the possibility of selection bias.

Whatever method is used to produce a random allocation sequence, it is important that allocation concealment is maintained. Methods to ensure the concealment of allocation may be as simple as using sealed opaque envelopes, [10] but the advent of larger and multi-centre trials and technological developments means that web-based randomisation has become the predominant method of assigning trial participants to treatment groups. Appropriate attention to this aspect of a clinical trial is essential as trials with poor allocation concealment produce estimates of treatment effects that may be exaggerated by up to 40%. [11]

The Interventions

The intervention being evaluated in any clinical trial should be described in sufficient detail so that clinicians could implement the therapy if they so desired, or researchers could replicate the study to confirm the results. Trials have traditionally evaluated the effects of one intervention but given the number of participants needed to produce reliable results and the time it takes (several years) to design and conduct RCTs, this approach is increasingly being seen as unacceptably inefficient. Approaches to improve efficiency include two-by-two factorial trials that study the effects of two interventions in the conduct of one trial and the use of master protocols and adaptive trials which are discussed in more detail below.

This may be a simple task if the intervention is a single drug given once at the beginning of an illness, or may be complex if the intervention being tested is the introduction of a process of care, such as the introduction of a medical emergency or rapid response team. [6] There are two additional areas with regard to the interventions delivered in clinical trials that require some thought by those conducting the trial and by clinicians evaluating the results, namely blinding and the control of concomitant interventions.

Blinding

Blinding, also known as masking, is the practice of keeping trial participants (and, in the case of critically ill patients, their relatives or other legal surrogate decision makers), caregivers, data collectors, those adjudicating outcomes and sometimes those analysing the data and writing the study reports, unaware of which treatment is being given to individual participants. Blinding serves to reduce bias by preventing clinicians from consciously or subconsciously treating patients differently on the basis of their treatment assignment within the trial. It prevents data collectors from introducing bias when recording parameters that require a subjective assessment (e.g. pain scores, sedation scores or the Glasgow Coma Scale score). Although many ICU trials cannot be blinded (e.g. trials of intensive insulin therapy cannot blind treating staff who are responsible for monitoring blood glucose and adjusting insulin infusion rates), the successful blinding of the Saline versus the Albumin Fluid Evaluation trial demonstrated the possibility of blinding even large complex trials. [2] Blinded outcome assessment is also necessary when the chosen outcome measure requires a subjective judgement. In such cases, the outcome measure is said to be subject to ascertainment bias. For example, a blinded outcome assessment committee should adjudicate the diagnosis of ventilator-associated pneumonia (VAP) and blinded assessors should be used when assessing functional neurological recovery using the extended Glasgow Outcome Scale; both the diagnosis of VAP and the assessment of the Glasgow Outcome Scale require a degree of subjective assessment and are therefore prone to ascertainment bias.

It has been traditional to describe trials as single blinded, double blinded or even triple blinded. These terms, however, can be interpreted by clinicians to mean different things, and the terminology may be confusing. [12] It is recommended that reports of RCTs include a description of who was blinded and how this was achieved, rather than a simple statement that the trial was ‘single blind’ or ‘double blind’. [13] Blinding is an important safeguard against bias in RCTs and, although not thought to be as essential as the maintenance of allocation concealment, empirical studies have shown that unblinded studies may produce results that are biased by as much as 17%. [10]

Concomitant Treatments

Concomitant treatments are all treatments that are administered to patients during the course of a trial other than the study treatment. With the exception of the study treatment, patients assigned to the different treatment groups should be treated equally. When one group is treated in a way that is dependent on the treatment assignment but not directly related to the treatment, there is the possibility that this third factor will confound the outcome. An example might be a trial of pulmonary artery catheters (PAC) compared with management without a PAC. If the group assigned to receive management based on the data from a PAC received an additional daily chest X-ray to confirm the position of the PAC, they could conceivably have other important complications, such as pneumonia, pulmonary oedema or pneumothoraces, noted earlier and this may affect the outcome in a fashion unrelated to the data available from the PAC. Maintaining balance in concomitant treatments is facilitated by blinding. When trials cannot be blinded, the use of concomitant treatments that may alter the outcome should be recorded and reported.

Master Protocols and Adaptive Trials

Traditional clinical trials have followed a fixed design from the start of participant recruitment until trial completion and study only one intervention. Interim analyses are few in number and used very conservative stopping rules focused exclusively on the primary outcome in the overall population. This approach has many advantages, including simplicity and transparency, which may make the trial results more compelling to clinicians. In recent years, interest in and the use of more complex trial designs has increased.

An adaptive trial uses information generated during trial conduct to alter subsequent operations in a pre-specified way. The change may be quite simple and easy to understand, such as changing the sample size, and in practice, most trials have an adaptive design as they allow early stopping for either efficacy or futility in response to recommendations from an independent data-monitoring committee. A less well-established but equally simple adaptive design is increasing the sample size due to a lower-than-expected event rate; an example of this is the PROWESS-SHOCK study where a predetermined increase in the sample size occurred in response to a lower-than-expected mortality rate in patients with septic shock. [14] More complex adaptive designs include changing drug doses or dropping or adding trial arms or drug doses, changing the proportion of patients assigned to each arm of a trial or changing the inclusion or exclusion criteria (all based on pre-specified criteria) are becoming more common in critical care. [15]

Master protocols include umbrella trials, basket trials and platform trials. All three are set up to share key operational aspects and design components, to achieve better coordination than can be achieved in single independent trials. An umbrella trial studies multiple targeted treatments in the context of a single disease, for example multiple different targeted treatments for different sepsis phenotypes.

A basket trial studies a single targeted treatment in the context of multiple diseases or disease subtypes. For example an immunotherapy might be tested in patients with sepsis, ARDS and multiple trauma.

A platform trial aims to study multiple targeted treatments in the context of a single disease, but in a (theoretically) perpetual manner, with treatments entering or leaving the platform based on pre-specified criteria. The evaluation of multiple interventions or strategies in a single platform trial in parallel, rather than in series, may be a more efficient strategy to assess treatments for some syndromes that commonly lead to critical illness. Trials using these designs, for example REMAP-CAP and RECOVERY came to prominence during the SARS-CoV-2 pandemic. [16], [17]

Registry Trials

Another innovation that can improve the efficiency of randomised trial is the randomised registry trial. Randomised registry trials use high-quality pre-existing registries to identify potential participants for trials and to collect outcomes and other data. This substantially reduces the workload under the traditional model where research staff or clinicians identify participants and then trial data is collected independently above any other ongoing data collection such trials are dependent on the existence of very high-quality databases that can conduct trials at much reduced cost. An example is the Thrombus Aspiration in ST-Elevation Myocardial Infarction in Scandinavia (TASTE) trial for which the incremental cost of including a patient in the trial was only $50. [18] The time-critical nature of many ICU trials means identifying patients from a registry is usually impractical but collecting both process and outcome data from an existing registry can still substantially reduce the cost of a trial.

Outcome Measurement

All clinical trials should be designed to detect a difference in a single primary outcome. In general, there are two types of outcomes, clinically meaningful outcomes and surrogate outcomes.

A clinically meaningful outcome is a measure of how patients feel, function or survive. [19] Clinically meaningful outcomes are the most credible endpoints for clinical trials that seek to change clinical practice. Phase III trials should always use clinically meaningful outcomes as the primary outcome. Examples of clinically meaningful outcomes include mortality and measures of health-related quality of life. In contrast, a surrogate outcome is a substitute for a clinically meaningful outcome; a reasonable surrogate outcome would be expected to predict clinical benefits based on epidemiological, therapeutic, pathophysiological or other scientific evidence. [19] Examples of surrogate endpoints would include cytokine levels in sepsis trials, changes in oxygenation in ventilation trials or blood pressure and urine output in a fluid resuscitation trial.

Unless a surrogate outcome has been validated, it is unwise to rely on changes in surrogate outcomes to guide clinical practice. For example, it seemed intuitively sensible that after myocardial infarction the suppression of ventricular premature beats (a surrogate outcome), which were known to be linked to mortality (the clinically meaningful outcome), would be beneficial; unfortunately, the CAST trial found increased mortality in participants assigned to receive antiarrhythmic therapy. [20] The process for determining whether a surrogate outcome is a reliable indicator of clinically meaningful outcomes has been described. [21]

Composite Outcomes

Mortality rate has traditionally been the patient-centred primary outcome for Critical Care trials. However, this generally means studying a very large number of patients and death is not the only outcome about which patients care. A composite outcome is one that adds together several outcomes (bad events) to generate a single measure. For example, the SMART trial used major adverse kidney events occurring within 30 days of randomisation (MAKE 30) as the primary outcome of a trial comparing balanced crystalloids with saline. [22] While using a composite outcome generally reduces the number of participants needed in a randomised trial, the components of the outcome measures should be equally important to patients and should move in the same direction as any treatment effect. Using MAKE 30 as an example, it is arguable that the three components, death, treatment with renal replacement therapy and doubling of creatinine, have very different levels of importance to patients. [23]

Analysis

Even when trials are well-designed and conducted, inappropriate statistical analyses may result in uncertain or erroneous conclusions. A detailed discussion of the statistical analysis of large-scale trials is beyond the scope of this chapter but certain guiding principles can be articulated:

- All trials should adhere to a predetermined statistical analysis plan because otherwise, the temptation to perform multiple analyses and report only those that support the preconceived ideas of the investigators may prove irresistible.
- Adaptive trials should follow a predetermined plan for statistical analysis of interim looks (‘adaptive analyses’) at the data and have predetermined statistical triggers for platform conclusions (superiority, inferiority, equivalence, futility and/or harm).
- The convention of accepting a P value of $<.05$ to indicate ‘statistical significance’ is based on the assessment of a single outcome. Assessing multiple outcomes increases the likelihood of finding a P value of $<.05$ purely due to the play of chance. Each trial should have a single predefined primary outcome measure. If more than one primary outcome measure is used, then the P value used to indicate statistical significance should be reduced. The simplest

method is to perform a Bonferroni correction, which divides 0.05 by the number of outcomes examined to determine the new level of statistical significance. Thus for two outcomes the *P* value must be below 0.025, and for three it must be below 0.017. The *P* value may also have to be reduced further if the trial employs interim analyses.

Clinicians should pay close attention to the analysis to make certain that a true intention-to-treat analysis is presented, and that any subgroup analysis is viewed with the appropriate amount of caution.

Intention-to-Treat Analysis

Trials should be analysed using the ‘intention-to-treat’ principle. This means that all participants are analysed in the group to which they were randomised regardless of whether they received all or any of the treatments to which they were assigned. To some readers the intention-to-treat principle may appear intuitively incorrect; it is reasonable to ask why patients who did not receive the intended treatment should be included in the analysis. The use of intention-to-treat analysis prevents bias arising from the selective exclusion of patients, termed ‘attrition bias’. In an appropriately sized trial, loss of patients at random should occur equally in both groups and the inclusion of those patients will not alter the result. If the loss of patients is occurring as a nonrandom event (e.g. because of protocol deviation or intolerance of the treatment in one arm of the trial) then the trial result will be different if the lost patients are excluded. Consider a trial of a 5-day course of L-NMMA for the treatment of patients with septic shock; in the trial, a number of patients who receive L-NMMA die in the first 24–48 hours and are excluded from the analysis as they have received only a little of the study treatment. A trial report based on the remaining patients who completed the treatment protocol (per-protocol analysis) will not give a true estimate of the effect of using L-NMMA in clinical practice. Although this is an extreme example, once a patient is included in a trial his/her outcome should always be accounted for in the study report.

Subgroup Analysis

Particular difficulties arise from the selection, analysis and reporting of subgroups. In traditional trials, parallel-group trials subgroups should be predefined and kept to the minimum number possible. When many subgroups are examined, the likelihood of finding a subgroup where the treatment effect is different from that seen in the overall population increases. A well-known example of this was the analysis of the treatment effect of aspirin in patients with myocardial infarction in the large Second International Study of Infarct Survival (ISIS-2) trial. Overall, the trial indicated that aspirin reduced the relative risk of death at 1 month by 23%. To illustrate the unreliability of subgroup analyses, the participants were divided into subgroups according to their astrological birth signs; the analysis showed that patients born under Libra or Gemini did not benefit from treatment with aspirin. [24] Although it is easy to identify this as a chance subgroup finding, this may be much harder when the choice of the subgroup appears rational and a theoretical explanation for the findings can be advanced. For example in the Gruppo Italiano per lo Studio della Streptochinasi nell'infarto miocardico (GISSI) trial, subgroup analysis suggested that fibrinolytic therapy did not reduce mortality in patients who had suffered a previous myocardial infarct. [25] Although this finding appears biologically plausible, subsequent trials have shown quite clearly that fibrinolytic therapy is just as effective in patients with prior infarction as in those without. [26]

The separation of patients into subgroups should be on the basis of characteristics that are apparent at the time of randomisation. The selection of subgroups using features identified after randomisation risks introducing bias as the patients have already been subjected to the different study treatments, and the subgroup analysis will therefore not be comparing like with like.

Tests of Interaction Versus Within-Subgroup Comparisons

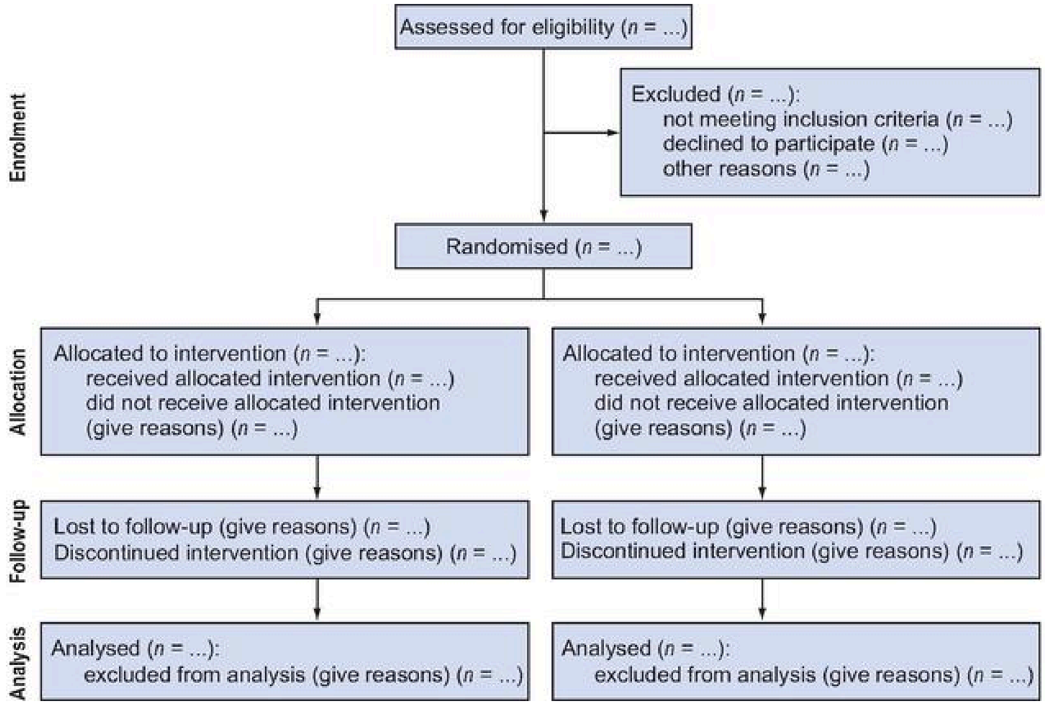
Even when subgroups are selected appropriately, many readers will be tempted to draw inappropriate conclusions from the results. As the trial will have been designed to examine the effect of the treatment on the primary outcome in the whole study population, the best assessment of the treatment effect in any subgroup will be the effect seen in the trial as a whole. When analysing a subgroup result, the investigators should seek to answer the following question: ‘Is the treatment effect in the subgroup different from the treatment effect seen in the remaining participants?’ This is a test of interaction or of heterogeneity. Often the investigators err and perform within-subgroup comparisons, which instead answer the question: ‘What was the effect of treatment A versus treatment B in this subgroup?’ Within-subgroup comparisons are more likely to lead to unreliable results. Journals such as the *New England Journal of Medicine* provide guidelines for the analysis and reporting of subgroup effects.[27]

Subgroups in (Adaptive) Platform Trials

As described above, these types of trials allow multiple interventions to be studied at the same time (‘platform’) and allow the trial to ‘learn’ from the data that accrue during the trial (‘adaptive’). In such trials repeated interim analyses, or adaptive analyses, are designed to identify subgroups of patients in whom treatments have a high probability of being superior, inferior or equivalent using Bayesian statistics. For example the REMAP-CAP trial was designed using a Bayesian inference framework in which a pre-specified Bayesian hierarchical model was frequently updated (exact frequency dependent on recruitment rates), to provide posterior probabilities of the primary outcome for each patient regimen-by-stratum subgroup. The thresholds for platform conclusions were predetermined as follows: Superiority declared if the posterior probability was greater than 99% that an intervention was superior to others in the same domain; inferiority if the posterior probability of superiority was less than 1%; and equivalence if a greater than 90% probability that odds of death for two interventions differ by less than 0.2.[17]

Reporting

The reporting of randomised controlled trials has been greatly improved by the work of the CONSORT (Consolidated Standards of Reporting Trials) group.[13], [28] The consort statement provides a framework and checklist that can be followed by investigators and authors to provide a standardised high-quality report.[28] An increasing number of journals require authors to follow the CONSORT recommendations when reporting the results of a randomised controlled trial. The group also recommends the publication of a structured diagram that documents the flow of patients through four stages of the trial – namely, enrolment, allocation, follow-up and analysis (Fig. 11.1). It is likely that the use of the CONSORT statement to guide the reporting of RCTs does lead to improvements, at least in the quality of reporting of randomised controlled trials.[29]



Enrolment
Assessed for eligibility (n = ...)
Excluded (n = ...):
not meeting inclusion criteria (n = ...)
declined to participate (n = ...)
other reasons (n = ...)
Randomised (n = ...)
Allocation
Allocated to intervention (n = ...):
received allocated intervention (n = ...)
did not receive allocated intervention (give reasons) (n = ...)
Allocated to intervention (n = ...):
received allocated intervention (n = ...)
did not receive allocated intervention (give reasons) (n = ...)
Follow-up
Lost to follow-up (give reasons) (n = ...)
Discontinued intervention (give reasons) (n = ...)
Lost to follow-up (give reasons) (n = ...)
Discontinued intervention (give reasons) (n = ...)
Analysis
Analysed (n = ...):
excluded from analysis (give reasons) (n = ...)
Analysed (n = ...):
excluded from analysis (give reasons) (n = ...)

The clinical trial flowchart is structured into four vertical phases labelled on the left as Enrolment, Allocation, Follow-up, and Analysis. The process begins at the top with a box labelled Assessed for eligibility with a placeholder for participant number. To the right is a box labelled Excluded, containing subitems for not meeting inclusion criteria, declining to participate, and other reasons, each with placeholders for values. An arrow leads downward to a central box labelled Randomised with a placeholder for the number of participants. From here, two branches diverge horizontally to two identical sets of boxes for the intervention arms. Each set begins with a box labelled Allocated to intervention, followed by lines for received allocated intervention and did not receive allocated intervention with a prompt to give reasons. Each allocation box is followed by a box labelled Lost to follow up and Discontinued intervention, both prompting for reasons and number of participants. The final row contains boxes labelled Analysed, with lines for number analysed and number excluded from analysis, again prompting for reasons. All boxes are uniformly shaped and connected vertically by arrows within each branch and horizontally from the randomisation point.

FIG. 11.1 Flow diagram of the progress through the phases of a randomised trial. (Reprinted with permission from Schulz KF, Altman DG, Moher D, CONSORT Group. CONSORT 2010 statement: updated guidelines for reporting parallel group randomised trials. *BMJ.* 2010;340:c332.)

Trials may report results using a number of values that, taken together, will give readers a full understanding of the trial results. For traditional frequentist trials, these may include a *P* value, confidence intervals and the number needed to treat (or harm). Trials using Bayesian analyses may report odds ratios with credible intervals along with posterior probabilities that one treatment is superior to another.

- *Probabilities:* the *P* value represents the probability that under a specified statistical model that a statistical summary of the data would be equal to or more extreme than its observed value. In very large trials, small and clinically insignificant differences may give rise to *P* value of less than .05 and, conversely, a moderately sized trial may report a clinically important difference with a *P* value that is close to or greater than .05; *P* values should not be viewed in isolation but should be assessed in combination with other measures, such as confidence intervals and the number needed to treat (or harm).
- *Posterior probability:* generally expressed as a probability ranging from 0 to 100% that one treatment is superior to another; posterior probability which is generated by Bayesian analysis, is derived from existing evidence (the prior probability) updated with data

accumulated during a trial. An example is the conclusion of a meta-analysis that there is an 89.5% probability that the use of balanced salt solutions in critically ill patients reduces mortality compared to saline. [30]

- *Confidence intervals:* these give an indication of the precision of the result. Whenever a trial reports a difference, it is reporting a difference found in a finite sample of the population of interest. If the same trial is repeated, it is highly likely that a slightly or very different result will be reported. If the trial is reporting a relatively small number of patients with the outcome of interest (small number of events) then the difference between the results may be large; if the trial reports a large number of events, then it is likely the two results will be quite close to each other. Confidence intervals give a range of values within which it is likely the 'true' result lies; they give an indication of the precision of the result. The most commonly quoted are the 95% confidence intervals; these are the limits within which we would expect 95% of study results to lie if the study were repeated an infinite number of times, though they are often interpreted to mean that we can be 95% confident that the 'true' result lies within these limits.
- *Credible intervals:* intervals generated by a Bayesian analysis which indicate the interval within which in an unobserved observation is expected to lie with a given, usually 95%, probability.
- *Number needed to treat (or harm):* a useful concept for clinicians is the number needed to treat (or harm). This is the reciprocal of the absolute difference in outcomes arising from two treatments. For example, in the ISIS-2 trial, patients randomised to intravenous streptokinase had an absolute reduction in mortality of 2.8%. Thus, the number needed to treat to prevent one death is 100/2.8 or 35.7 patients. As the trial was very large with a large number of events (17,187 participants and 1820 deaths), this relatively small absolute reduction in mortality (2.8%) yielded a P value of less than .000001. The same calculation can be performed to calculate the number needed to harm. For example in the CRASH trial, patients with traumatic brain injury treated with high-dose steroids

had a 3.4% increase in the absolute risk of death. The number needed to harm is calculated as 100/3.4, or one extra death for every 29.4 patients treated with high-dose corticosteroids. Again, as this was a large trial (10,008 participants and 1945 deaths) the P value is small (P =.00001).

Ethical Issues Specific to Clinical Trials in Critical Care

The ethical principles guiding the conduct of research in critical care are outlined in the International Ethical Guidelines for Health-Related Research Involving Human Subjects, [31] in addition country-specific guidelines are provided by various national bodies. The ethical principles of integrity, respect for persons, beneficence and justice, should be considered whenever research is conducted and an appropriately convened human research ethics committee or the equivalent should assess all research to ensure adherence to these principles. As the potential participants in critical care research are particularly vulnerable, owing to the nature of the conditions and the limitations to communication that exist, special consideration needs to be given to a number of areas including informed consent.

Informed Consent

That all mentally competent participants in clinical research should give informed consent prior to entering a study is an important ethical principle. This is rarely possible for people suffering from critical illness, where the disease process (e.g. traumatic brain injury, encephalitis and severe hypoxaemia) or the required treatment (e.g. intubation and use of sedative medications) may make it impossible to obtain informed consent. Even awake, alert patients may not be able to give fully informed consent when they are facing stressful and potentially life-threatening situations. [32] This applies equally to surrogate decision makers. However, the treatment of critically ill patients can be improved only through the conduct of research and on many jurisdictions, this has been recognised by making special provisions for consent in emergency research, including research on the critically ill. In some circumstances, it may be ethical to allow a waiver of consent for research involving treatments that must be given in a time-dependent fashion (e.g. in the setting of cardiac arrest). A waiver of consent may improve recruitment into clinical trials; it is unclear whether this approach is universally acceptable. Other ethically acceptable approaches for time-critical treatments are to allow deferred consent, consent to continue or opt-out consent, where patients are included in the study and consent or a request to opt out is sought from the patient or the relevant surrogate decision maker as soon as practical. Neither approach is without problems.[33]

Critical Appraisal

Clinicians reading reports of randomised controlled trials should use a structured framework to assess the methodological quality of the trial and the adequacy of the trial report. They should also address the magnitude and precision of reported treatment effects and ask themselves whether the results of the trial can be applied to their own clinical practice. There are a number of resources available to assist clinicians in this task, notably the Users' Guides to the Medical Literature, originally published in *JAMA* and the Critical Appraisal Skills Program from Oxford, United Kingdom, both of which are freely available on the Internet.[34],[35] These resources provide a structured framework that allows any reader to perform a systematic critical appraisal of almost any piece of medical literature including platform trials.[36] A checklist is provided for the appraisal of randomised controlled trials (Box 11.1).

Box 11.1

Critical appraisal checklist for randomised controlled trials

I. Are the results of the study valid?
   Primary guides: Was the assignment of patients to treatments randomised?

1. Were all patients who entered the trial properly accounted for and attributed at its conclusion?
2. Was the follow-up complete?
3. Were patients analysed in the groups to which they were randomised?

Secondary guides: Were patients, health workers and study personnel ‘blind’ to treatment?

1. Were the groups similar at the start of the trial?
2. Aside from the experimental intervention, were the groups treated equally?

II. What were the results?

How large was the treatment effect?

1. How precise was the estimate of the treatment effect?

III. Will the results help me in caring for my patients?

Can the results be applied to my patient care?

1. Were all clinically important outcomes considered?
2. Are the likely treatment benefits worth the potential harms and costs?

From Centre for Health Evidence. *Users’ Guides to Evidence-Based Practice* . http://www.jamaevidence.com ; 2007.

Observational studies

Although RCTs are the optimal study design for deciding whether or not a treatment ‘works’, not all research questions can be addressed with this type of study. When the disease is rare, the outcome is rare or the treatment may be associated with harm, other study designs may be more appropriate. In these circumstances, a cohort study or case-control study may be used to explore potential associations between exposure to a treatment and the occurrence of outcomes.

Descriptive Studies

Case reports, case series and cross-sectional studies are all examples of descriptive studies. These types of studies may be important in the initial identification of new diseases, such as HIV/AIDS[37], [38] and severe acute respiratory syndrome (SARS).[39] The purpose of these studies will be to describe the 'who, when, where, what and why' of the condition, and therefore further the understanding of the epidemiology of the disease. It is important that clear and standardised definitions of cases are used so that clinicians and researchers can identify similar cases from the information provided. Although there are some famous examples where data from simple observational studies have been used to solve particular problems,[40] in general only very limited inferences can be drawn from descriptive data. In particular, it is dangerous to draw conclusions about 'cause and effect' using data from descriptive studies alone.[41]

Analytical Observational Studies

There are two main types of analytical observational studies: case-control studies and cohort studies.

Case-control studies are performed by identifying patients with a particular condition (the 'cases'), and a group of people who do not have the condition (the 'controls'). The researchers then look back in time to ascertain the exposure of the members of each group to the variables of interest.[42] A case-control design may be appropriate when the disease has a long latency period and is rare. Cohort studies are performed by identifying a group of people who have been exposed to a certain risk factor and a group of people who are similar in most respects apart from their exposure to the risk factor. Both groups are then followed to ascertain whether they develop the outcome of interest. Cohort studies may be the appropriate design to determine the effects of a rare exposure and have the advantage of being able to detect multiple outcomes that are associated with the same exposure.[43]

Both types of observational studies are prone to bias. In particular, although it is possible to correct for known confounding factors using multivariate statistical techniques, it is not possible to control for unknown or unmeasured confounding factors. There are a number of other biases that may distort the results of observational studies; these include selection bias, information bias and differential loss to follow-up.[43,44] Critical appraisal guides for observational studies are available to help readers assess the validity of these studies.[45] These limitations and inherent biases mean that observational studies may not always provide reliable evidence to guide clinical practice, although it has been argued that this is not always the case.[46,47]

Systematic Reviews and Meta-Analyses

Systematic reviews have been proposed as a solution to the problem of the ever-expanding medical literature.[48] A systematic review uses specific methods to identify and critically appraise all the RCTs that address a particular clinical question and, if appropriate, statistically combine the results of the primary RCTs to arrive at an overall estimate of the effect of the treatment. By systematically assembling all RCTs that address one specific topic, methodologically sound systematic reviews can provide a valuable overview for the busy clinician. They play an important role in providing an objective appraisal of all available evidence and may reduce the possibility that treatments with moderate effects will be discarded owing to false-negative results from small or underpowered studies.[49] The use of meta-analysis could have resulted in the earlier introduction of life-saving therapies, such as thrombolysis for acute myocardial infarction.[50] By using systematic methods, meta-analyses can provide more accurate and unbiased overviews, drawing conclusions that are often at odds with those of ‘experts’ and narrative reviews.[51,52]

In spite of these advantages and benefits, there are still problems with the conduct and interpretation of meta-analyses. Trial-level meta-analyses may include trials that are subsequently retracted due to errors or even fabrication. Patient-level meta-analyses (also known as independent patient data meta-analyses), in which researchers gather together and aggregate trial databases, may overcome these concerns but are expensive and time consuming to conduct, and not all investigators are prepared to share their trial databases. Like all research, meta-analyses need to be performed with attention to methodological detail. There are guidelines for performing and reporting systematic reviews.[53,54] It is clear that in the critical care literature, these guidelines are not always followed.[55] Clinicians should critically appraise the reports of all systematic reviews and meta-analyses regardless of the source of the review, using an appropriate guide.[56,57] Problems with interpretation can arise when the results of meta-analyses are at odds with the results of large RCTs that address the same issue[58,59]; this is not uncommon, and clinicians will have to compare the methodological quality of the meta-analyses and the RCTs included in it with the validity of the large RCT to decide which provides the most reliable evidence.[2,60]

Ethics

Victoria Metaxa

The Role of Medical Ethics in Intensive Care

Ethics is a broad term that covers the study of the nature of morals and the specific moral choices to be made. *Normative* ethics attempts to answer the question, ‘Which general moral norms for the guidance and evaluation of conduct should we accept, and why?’ [1] In simpler terms, normative ethics asks the question, ‘What is morally right or wrong?’ and explores the set of questions that originate when we consider a course of action in terms of morality (in contrast to *metaethics* , the study of the origin and meaning of ethical concepts which asks, ‘What is morality?’).

Ethics is an inherent and inseparable part of clinical medicine, as the physician has an ethical obligation to (1) benefit the patient, (2) avoid or minimise harm and (3) respect the values and preferences of the patient. [2] The intensive care unit (ICU) is a high-pressure and high-emotion environment, where expensive care is delivered by highly qualified personnel to patients suffering from potentially life-threatening diseases. The ICU is also ethically charged: bed availability is limited, making high patient throughput important; time-critical, treatment-limiting decisions are necessary, often without prognostic certainty and without being able to ascertain patient wishes. When medical criteria alone are insufficient in deciding what is the right thing to do, healthcare professionals are faced with ethical challenges that can lead to moral distress, particularly around end-of-life care. [3]

In this chapter, we will explore the most common approaches to bioethics, describe the challenges faced by intensive care specialists and provide an ethical decision-making aid.

Ethical Theories

The most influential ethical approach is known as 'principalism', with Beauchamp and Childress giving the embryonic field of bioethics a shared method for addressing its challenges during the 1970s and 1980s. They advocated an approach that is based on four principles:

1. Respect for autonomy (patient's right to self-determination)
2. Beneficence (the moral obligation to promote the patient's welfare)
3. Non-maleficence (avoidance of harm to the patient)
4. Justice (fair, equitable and appropriate distribution of healthcare resources in society).

These four principles represent a 'common morality' in the sense that they are generally respected within societies around the world. They suggest a coherent, consistent way of addressing issues arising in healthcare by providing a 'basic moral language and a basic analytic framework that all interested in biomedical ethics can share'. [4] The criticism against principlism arises mainly from the difficulties encountered when applied in practice often leading to contradiction: granting a patient's request for an unorthodox treatment may respect their autonomy but may also result in harm (contradicting non-maleficence) and time/resources taken away from other patients (contradicting the principle of justice). Another objection is that when the four principles clash, there is no clear guidance on how to balance them. Although Beauchamp and Childress claim that the four principles are of equal value, autonomy has gained a central place in principlism, a stance criticised as overly Westernised and not applicable to other family-orientated cultures. [5] In any case, they provide a useful reference in any ethical discussion, but they should not be viewed as the final word but rather than a starting point.

There are other approaches to the ethical problems encountered in medicine, with considerable attention being paid in recent years to the ‘ethics of care’. [6] *Care ethics* criticises traditional bioethics which focuses on individual rights and individual autonomy; instead, it centralises relationships, interdependency and care. Although not without its criticisms, care ethics promote caring relationships, and so appear to be in the heart of the patient-doctor but mainly in the nurse-patient relationship. Focusing on attentiveness, trust and responsiveness to need, rather than fairness and individual rights, it is a relatively new moral theory that could be used to supplement the four principles.

Decision-making

Decisions about treatment, particularly about limiting life-sustaining treatment are common in ICU and often involve patients whose reasoning capacity is impaired. Capacity assessment is central to good medical practice and is based on the principle of autonomy, which ensures that people should be able to make their own choices about whether or not to accept medical interventions. Four abilities are necessary when assessing a patient’s decisional capacity [7] :

1. the ability to communicate a choice
2. the ability to understand relevant information
3. the ability to appreciate how this information applies to one’s current and future situation
4. the ability to give comprehensible reasons for the decision.

Clinicians should evaluate decision-making capacity in the context of the specific treatment that is discussed at the specific moment, and all patients should be presumed competent to make their own decisions unless proven otherwise.

When illness, injury or medication impedes a patient’s ability to make choices, someone else assumes responsibility for the medical decision-making. In such cases, advance care planning (ACP), the substituted judgement and best interest standards may be used. [8] The latter two standards are beyond the scope of this chapter.

Ethical Climate

Defined by Victor and Cullen, ethical climate is ‘the shared perceptions of what ethically correct behaviour is and how ethical issues should be handled’, [9] which in healthcare has been translated as the ‘implicit and explicit values that drive healthcare delivery and shape the workplaces in which care is delivered’. [10] Ethical climate has been found to influence patient safety, job satisfaction, perceived workplace support and commitment and intent to leave a position. [11] Since decisions in the ICU, especially around the end of life, are to some extent value-laden and not purely knowledge- and fact-based, achieving a climate based on mutual respect, which encourages clinicians to express their opinions, values and beliefs is of utmost importance. However, achieving such a climate is challenging not least because dedicated, comprehensive measuring tools were lacking. Recent research on ethical decision-making climate in the ICU focused on three key domains: (1) respectful interdisciplinary collaboration and communication; (2) authentic leadership by physicians; (3) a good ethical work environment, and proposed a validated measurement instrument to assess it. [12]

Perceptions of ethical climate appear to be influenced more by local and context-specific factors, rather than country (e.g. low- or high-income countries) or the specific study population (i.e. ICU compared to other settings). [11] However, consistently, physicians and nurses have different views on the ethical decision-making process and interdisciplinary collaboration, presumably due to their different roles in decisions regarding ICU treatment. [13] Physicians perceive collaboration in decision-making more positively than ICU nurses and this discrepancy persisted, if not worsened, since the COVID-19 pandemic. [14] Given that the quality of the ICU ethical climate is associated with the intention to leave one’s job, [15] physicians’ tendencies to overestimate it may contribute to the worsening critical care nursing workforce crisis. [16] Improving the ethical decision-making climate by targeting attitudes, beliefs and culture among staff rather than only the practices themselves could be pivotal in preventing and decreasing staffing shortages and, consequently, improving patient outcomes.

Shared Decision-Making

Shared decision-making (SDM) is defined as a cooperative process between clinicians and patients and, often in the ICU, their surrogates. It facilitates treatment decisions by combining the clinician’s knowledge and expertise with the patient’s life values and goals. [17] Many critical care professional organisations recommend SDM as a central component of patient-centred care in ICU and suggest that clinicians should (1) engage in a shared decision-making process with patients and families to define overall goals of care (including decisions regarding limiting or withdrawing life-prolonging interventions) but also when making major treatment decisions that may be affected by personal values, goals and preferences; (2) use as their ‘default’ approach a shared decision-making process that includes three main elements: information exchange, deliberation and making a treatment decision; (3) tailor the decision-making process based on the preferences of the patient or surrogate; (4) be trained in communication skills. [17]

Death and Dying

In the past, death was something to be expected, unavoidable and hence accepted. Medical advances have changed the attitudes towards death and in recent years death has become something to be denied, avoided or controlled. Particularly in the ICU, technological developments have enabled multi-organ support even in situations when the therapeutic goal cannot be reached or when the achieved outcome is not concordant with the patient’s wishes. More than 80% of ICU deaths occur after conscious decisions to withdraw life-sustaining therapy, but the transition from active, invasive interventions to comfort care is often fraught with misunderstandings, conflict and moral distress. [18], [19]

Withholding and Withdrawing Life-Sustaining Treatment

The equivalence between withdrawing and withholding life-sustaining treatment has been a matter of intense debate, with ethicists proposing that these procedures are equivalent, while clinicians argue against it.[20], [21] This moral equivalence is supported in professional guidelines and by international decision-support tools but despite ethicists' arguments favouring this theory, critical care clinicians appear more uncomfortable withdrawing treatment than withholding it, making a distinction that seems to persist through time.[22] Several explanations have been offered for the rejection of the equivalence theory in practice, such as the perceived moral difference between an act (withdrawing) and omission (withholding); the stronger association between an action and the result (death); and the short temporal link between the two.[23] Furthermore, physicians find some types of therapy more difficult to withdraw than others, with the removal of the endotracheal tube being the least practised act of withdrawal globally.[24]

Central in the debate of the 'equivalence theory' is the *Doctrine of Double Effect* , a principle often used in contemporary healthcare ethics. It refers to the two effects that can potentially arise from a single action: one that is desirable and intended, and another that may be foreseeable but undesirable and unintended. The doctrine is particularly relevant where the foreseen result of an action is morally serious in nature, for example when it is temporally associated with a patient's death. It has mainly been used as an ethical rationale for providing relief of pain and other symptoms with sedatives, even when this may have the foreseen (but not intended) consequence of hastening death.[25] Although the doctrine has been philosophically contested,[26] it is still widely morally admissible and legally supported.

Advance Care Planning

The purpose of advance care planning (ACP) is to ensure goal-concordant care near the end of life for patients who lack decisional capacity. It has significant theoretical advantages, as it allows patients to refuse therapies and plan their future care, ensuring that the treatments they receive are consistent with their values and wishes. However, studies have failed to show that ACP is associated with influencing medical decision-making at the end of life, enhancing the likelihood of goal-concordant care or improving patients' or families' perceptions of the quality of care received.[27,28] Furthermore, its legal status is not universal, with some countries having specific laws but many lacking a clear legal framework.

The inability of ACP to achieve the desired outcomes, even when legally binding in theory, represents the gap between hypothetical scenarios and the decision-making process in clinical practice settings.[29] Its success depends on (1) the patients being able to predict how they would like to be treated when they lose capacity, and to articulate/document their values and goals in specific, hypothetical future scenarios; (2) clinicians being able to identify these documents and to honour previously expressed wishes, even if they come in direct opposition to their own medical judgement; and (3) surrogates to be able to invoke substituted judgement and base their treatment decisions on the patient's prior stated preferences.[29] In reality, patients' preferences are rarely static but fluctuate depending on age, socio-economic status, physical and cognitive function and perceived caregiver burden. Advance directives are often poorly documented or vague and cannot apply to the specific situation in question. Clinicians and surrogates find it difficult to extrapolate treatment decisions in the present from hypothetical discussions that occurred in the past and disentangle their own preferences and emotions from those expressed on a piece of paper.[30,31] To be applicable and relevant, ACP should be a process and not a moment's decision, should follow the patient's journey in life and reflect the fact that treatment choices near the end of life are not simple, linear or foreseeable but frequently complex, uncertain, emotionally laden and fluid.

Prioritisation of scarce resources

In many industrialised countries, social goods – including, education, defence, infrastructure and healthcare – are funded from a common pool. Although the need for such goods is limitless, the resources available are not, so inevitably some form of prioritisation is required. The terms *resource allocation* and *rationing* can be used interchangeably, despite the more neutral connotation of the former and the higher emotional charge of the latter. Rationing in healthcare is defined as 'the allocation of resources in the face of limited availability, which necessarily means that beneficial interventions are withheld from some individuals’.[32] Rationing decisions are present in daily ICU practice both at a macro- (governmental budgetary decisions) and a micro-level (bedside clinical decisions): from the number of critical care staff and beds available in a country, to the time spent with each patient and family, and the types of imaging, antibiotics and off-licence drugs that are ordered, rationing appears unavoidable.[32-34] Many principles could form the basis of rationing decisions in health care, each of which represents a different interpretation of distributive justice. For example, the following have been proposed as valid material principles of distributive justice: (1) to each person an equal share (2) to each according to need, (3) to each according to effort, (4) to each according to free market conditions, (5) to each to maximise overall usefulness.[1]

The recent COVID-19 pandemic put a tremendous strain on many healthcare systems and highlighted the need for preparedness when demands on acute and critical care services outstrip capacity. Many governments, professional societies and experts proposed triage guidelines to prioritise scarce resource allocation.[35-38] Although the various guidelines differed in detail, the majority were firmly grounded in the utilitarian goal of efficiency: maximising the number of lives saved and, in some cases, maximising the number of life-years saved. Other proposed criteria considering life stages, rewarding social behaviour or healthcare status or giving priority to the worst off have been subject to controversy.[39] In the quest to find the optimal prioritisation tool, one should consider whether a transparent, thoughtful, but ethically problematic triage protocol that relieves clinicians of the burden of making difficult choices without guidance is better than no protocol at all.[40], [41] Most importantly, any protocol should have prospectively defined criteria and protocols announced in advance, be explicit, fair and just without biases and provide maximum consistency in decision-making.

Treatment limitation and palliative care

Sarah Cox and Phoebe Wright

Palliative Care

The World Health Organisation defines palliative care as an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual (Box 13.1).[1]

Box 13.1

World Health Organisation's definition of palliative care

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends neither to hasten nor postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death

- Offers a support system to help family members cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counselling if indicated
- Will enhance quality of life, and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better

From Sepúlveda C, Marlin A, Yoshida T, et al. Palliative care: the World Health Organisation's global perspective. *J Pain Sympt Manage* . 2002;24(2):91–96

Palliative care clearly has a place in the care of patients identified as dying in the intensive care unit (ICU). In addition, the principles of palliative care may be appropriate for patients with life-limiting diseases admitted to ICU for treatment of reversible causes such as neutropenic sepsis as a consequence of palliative chemotherapy. The palliative care team may also have a role in the care of patients with long-term conditions being considered for ICU admission. This chapter reviews the issues around the identification and management of palliative and end-of-life care for ICU patients. It will also address some of the practical, ethical and emotional issues that arise.

Pre-Admission to ICU

Admission to the ICU requires a judgement about the likelihood of benefit for the individual patient. While this is often a discussion between the ICU or critical care outreach team, the usual medical team and the patient and family, the palliative care team may have an important role to play. Firstly, they can be part of a discussion about the appropriateness of aggressive treatment. Secondly, it may be helpful to underline that if ICU care is not the chosen course of action, there is another specialist team who will be involved to ensure good symptom control and emotional support. Their expertise in communication can be useful in clarifying goals aligned with the patient's wishes, if known, including access to pre-existing advance care plans from community health care teams. They can support family and ward staff with an alternative approach to care. They may become the point of contact for the family providing continuity and reassurance in what is often an emotionally fraught situation.

Patients in the ICU Who Are Dying

Around 5% of deaths in the United Kingdom and 17% of deaths in the United States occur in the ICU. [2] Not all of these deaths could or should be predicted, but the proportion that follows a period of treatment withdrawal is increasing across Europe. [3] This suggests an identifiable end-of-life phase, which could be managed with palliative care principles in mind, or as shared care with a specialist palliative care team.

There is great variability in end-of-life practices in ICUs worldwide. Withdrawal of treatment is seen more commonly in North America, Australia and New Zealand and Northern Europe than in Latin America and Africa. [4] Death, after failed CPR, was more common in Africa, Latin America and Southern Europe. [4] Differences can also be identified between services in a single country or even between teams in one ICU. [5] These differences could in part be explained by the availability of ICU beds and staff and admission criteria, but an important factor in end-of-life practice on ICU is the attitude of ICU staff and cultural differences in expectations of treatment.

Scales such as APACHE IV have been developed to help predict outcomes of ICU intervention, [6] but they are not sufficiently precise to be helpful in end-of-life decision-making for an individual. Frequently ICU admission represents a therapeutic trial with both clinicians and family sustaining hope until it is clear the trial has failed. Only then, which may be very late in the acute illness, will a transition to the goals of palliative care be considered appropriate. There may be an opportunity therefore to communicate uncertainty earlier on in the ICU stay so that active and palliative care can occur together.

What constitutes a good death depends on the role (patient and relative healthcare professional) and the views of the individual which may be influenced by their cultural and religious background. For patients dying outside the ICU, there are some common themes about what makes a good death including freedom from pain and other symptoms, maintaining a sense of person, a feeling of closure and the ability to continue to give to others [7] (Box 13.2). For patients dying in ICU some of these will be challenging to support or achieve due to the patient being sedated or unconscious. In addition, many of these patient surveys come from Western societies and may not reflect the wishes of patients from other cultures.

Box 13.2

Patients' and families' priorities for a good death

Patients' priorities [7]	**Families' priorities** [8]
Control of pain and other symptoms Clear decision-making Feeling of closure Being seen and perceived as a person Preparation for death Being still able to give something to others	Honest empathic communication Compassionate family support Clear explanation at family meetings Shared decision-making Flexible visiting Avoiding futile medical intervention Control of symptoms

Relatives of patients dying in the ICU value empathic and honest communication; compassionate support; meaningful explanations at family meetings; shared decision-making; and flexibility in visiting the ICU [8] (Box 13.2). Satisfaction of families is also related to clarity around the processes of limiting treatment, with trials of treatment being explained and withdrawal or withholding of treatment occurring as expected. [9]

Finally, ICU nurses prioritise managing symptoms; promoting earlier cessation of treatment or not initiating aggressive treatment at all; knowing and following their patients' wishes for end-of-life care and communicating effectively as a health care team.[10]

Cultural Differences and End-of-Life Care in ICU

Culture,[11] religion[12] and geographical region[13] of the patient, family and clinician all have an impact on the views, practices and decision-making around end-of-life care. Within an ICU setting the areas that are particularly impacted include decision-making and the prevalence of withholding and withdrawal of treatment.

Within the Western culture, the ethical principle of autonomy is central to clinical decision-making[14] and is protected in law through the concept of informed consent. However other cultures, including in Asia, demonstrate a more collectivist culture where decisions are made through relational autonomy and familial involvement,[11,15] with senior family members having a more dominant role in decision-making than the patient.[16] Other cultures, for example, Southern Europe, take a more paternalistic approach with physicians often leading decision-making[4] and in Japan and China, there is a preference for a passive decision-making style with 'trusting my physician' as one of the tenets of a good death.[7]

There are also cultural differences around truth telling, with some cultures including Hispanic, Asian and Middle Eastern, where families (and sometimes clinicians) would not want to tell a patient about a terminal diagnosis in order to protect them from hearing bad news.[11,17]

The cultural backgrounds of healthcare professionals, patients and families have all been shown to impact treatment decisions within ICU.[17,18] The Ethicus-2 Study demonstrated variation in the decisions made by healthcare professionals around the withholding and withdrawing of treatment of ICU patients in different cultures,[4] as discussed above. Some examples of withholding or withdrawal of treatment are more culturally sensitive than others. For example, whilst in America the role of artificial nutrition is reviewed when a patient is dying, in Asia and some Islamic countries this is seen by healthcare professionals as basic care and not a medical treatment. [19]

The cultural background of patients and families can impact their views around withholding and withdrawing treatment for many reasons. [20] An example for African Americans is that historical discrimination and mistrust of the medical establishment contribute to patients and families pushing for aggressive treatment. [17]

Decision-Making for Patients at the End-of-Life

Involvement of Patients

In the 1990s the SUPPORT study team reported their prospective observation of over 9000 seriously ill hospitalised patients. [21] The authors identified overaggressive management, inadequate pain control and poor communication amongst a significant number of those who went on to die. There was evidence that physicians were often not aware of patients' wishes around medical care. Thirty years later, there is evidence that physicians remain very poorly informed about their patient's wishes, even where deterioration is predictable. [22]

The majority (over 80%) [23] of patients requiring admission to ICU will be unable to engage in discussions about treatment choices, and most will not have discussed their wishes with relatives or recorded them in writing. [24] Occasionally, a valid and applicable advance decision to refuse treatment (ADRT) exists; patients have discussed their preferences for treatment with close family; have previously appointed a lasting power of attorney (LPA), or have an advance care plan (ACP) in place.

ADRTs and LPAs are both legal documents in many countries and are put in place whilst a person still has the capacity to help decisions to be made if and when they lose capacity. ADRTs set out what treatments would and would not be acceptable to the patient in specific circumstances; this can include interventions such as artificial hydration and nutrition. LPAs allow the patient to appoint people to make decisions for them when they no longer have the capacity. In the United Kingdom, there are two types of LPA – for health and welfare and for property and financial affairs. The nominated person then acts as the voice for the patient when decisions are being made about their health. Similar documents to the LPA are available in other countries but are often known by alternative names, for example Enduring Power of Attorney in Australia.

ACP is defined as ‘a process that supports adults at any age or stage of health in understanding and sharing their personal values, life goals and preferences regarding future medical care’ with the goal of helping to ‘ensure that people receive medical care that is consistent with their values, goals and preferences during serious and chronic illness’. [25] This involves communication between patients, their family or others and their healthcare provider.

Patients with ACPs have decreased ICU admissions and reduced ICU length of stay. [26] There are two key times for the ICU team to consider engaging patients and families in ACPs. Firstly, when critical care outreach teams review patients on the wards prior to admission, the patient might still be well enough to engage in such conversations. Secondly when patients are discharged from ICU their ACP and treatment escalation plan should be reviewed. The recording of ACP in the United Kingdom is as low as 5% in patients presenting with an acute medical emergency. [27]

Where patients are able to discuss options for treatment, it should be considered that they may have a variable understanding of medical interventions. Both patients and clinicians tend to overestimate the likelihood of success, with optimism on the part of the patient, and a reluctance to be pessimistic on the part of the clinicians. [28] However, discussions about treatment that include details of the likely outcome and potential burden can significantly reduce patient preferences for those treatments where the medical benefit is uncertain. [29]

Involvement of Families in Decision-Making

Where decisions are about quality of life versus quantity of life it is very important to understand the patient’s views. However, most patients in ICU are not able to take part in decision-making. The views of the patient can theoretically be accessed through relatives or friends and relatives value the opportunity to be involved. [30] However, we must accept that this is a less-than-ideal alternative. Not all family members wish to be involved in decision-making, but when they do they may struggle to take on board the consequences of decisions or may be left with feelings of guilt or even post-traumatic stress. [31] They may also have difficulty differentiating their own and the patient's wishes, especially in certain circumstances. [32] When limitations of treatment are being discussed, relatives are able to identify patient preferences with an agreement of 80% or greater in situations where the impact of the physical insult is either mild or devastating. [33] However, there is a dramatic drop in agreement (down to around 60%) for more ambiguous scenarios associated with long-term physical or cognitive morbidity. In these situations, relatives are more likely than patients to identify the clinical outcome as acceptable.

Effective, frequent and timely communication with relatives increases satisfaction with care and reduces anxiety in bereavement. [34] Insufficient time spent communicating with families results in a poor understanding of the diagnosis, prognosis and plan of care and increased conflict. [35] Time spent is not, in itself, enough, and far more important is the clinicians' ability to elicit and respond to families' views and concerns. Families judge the quality of the discussion, at least in part, by how much time they are allowed to speak rather than encouraged to listen. [36] Although the communication skills of ICU staff may be excellent, the additional resources of the palliative care team can also be useful in these situations.

Involvement of Other Health Professionals in Decision-Making

ICU nurses often feel frustrated by the medical plan especially when, in their view, conflicting or over-optimistic messages are given to patients or family members. [37] In contrast, physicians are reported to feel the burden of making decisions about limiting treatment and that 'it's a lot easier to say it than to do it'. [38]

Collaboration between these professionals has the potential to produce better-informed decisions, which can lead to greater satisfaction with care for patients, families and the professionals involved.[32] Not surprisingly inconsistent messages and non-collaborative inter-professional behaviours result in family dissatisfaction.[39] Shared decision-making will reduce the burden of decision-making on senior ICU physicians, but it still usually remains their ultimate responsibility. Three studies of collaborative decision-making involving health professionals and family members have demonstrated the additional benefits of reduced length of ICU stay and lower costs with no increase in mortality.[40]

There is much published on the involvement of other professionals in end-of-life decision-making such as social workers, chaplains[41] or palliative care clinicians.[42] Proactive palliative care involvement on ICU rounds for high-risk patients is associated with earlier and more frequent family meetings and shorter lengths of stay.[42]

The involvement of clinical ethicists has been demonstrated to improve the satisfaction of both health care professionals and families and to reduce the length of ICU stay and costs for patients who died.[43]

Withdrawal of and Withholding Treatment

In many cultures, patients identify the avoidance of inappropriate prolongation of dying in their definition of what a ‘good death’ might look like.[44] There is agreement in the United States and northern Europe that where treatment is not going to succeed it should be withheld or withdrawn.[45–47] However, differences have been measured in what ICU physicians believe they should do and what actually happens, with physicians identifying a significantly greater need for withholding or withdrawing treatment than their practice demonstrates.[48] The ethics around withholding and withdrawing treatments are discussed in Chapter 12 .

Given such variations in practice and the potential for different interpretations of intentions in withdrawing or withholding life-sustaining treatment, excellent communication between the multi-professional team and the family, and clear documentation of the intent and decision-making process leading to it are paramount (Box 13.3).

Box 13.3

Recommendations for managing the transition from active to palliative care in the ICU

- Inclusive and collaborative decision-making
- Consistent communication with family that begins early
- Identification of trials of therapy with timed reassessment against clinical milestones
- Concurrent attention to symptom control, spiritual and psychological support of patient and family
- Clarity about withholding and withdrawing treatment
- Guidance for ‘stepping down’ to general hospital wards
- Inclusion of organ donation in consideration
- Assessment of bereavement risk for onward referral if appropriate
- Support of staff
- Clarity around ceilings of treatment

Symptom Control

Patients in the ICU experience a high level of symptoms, including pain, dyspnoea and anxiety. [21] Symptom assessment usually involves taking a detailed history from the patient to understand the cause and severity of the symptom. In many ICU patients at the end-of-life, this is not possible and so physiological variables and behavioural observations are used as surrogate markers, such as heart rate and respiratory rate. The use of validated pain scales such as the Behaviour Pain Scale [49] may provide more objective records of pain to direct changes in the dose of symptomatic medication. The involvement of the specialist palliative care team may be useful when the situation is unclear or symptoms prove difficult to control.

Dyspnoea correlates most strongly with tachycardia and tachypnoea [50] and may be treated symptomatically with opioids [51] with the addition of benzodiazepines [52] to reduce anxiety if necessary. Treatments such as oxygen, corticosteroids and diuretics may be appropriate if they improve symptomatic control of breathlessness. Signs of agitation, anxiety or behavioural markers of pain that do not respond to opioids and may be caused by general distress can be treated with benzodiazepines. Specialist palliative care input may be helpful if symptoms fail to respond to usual measures.

The choice of opioid and benzodiazepine varies; it is important for units to use the particular drug most familiar to them. Morphine is the first line but should not be used in patients with moderate to severe renal impairment as accumulation can result in additional symptoms. Fentanyl or alfentanil are common alternatives in this situation. Drug doses should be titrated against symptoms and escalated in response to documented markers of distress. The intention should not be to hasten death.

There has been concern about the doses of opioids and benzodiazepines required to control dyspnoea and agitation, especially in rapid weaning or extubation, and whether in fact, these medications themselves bring about the patient's death. However small studies in ICU show that the doses of opioids and sedatives required for symptom control are relatively modest [53], [54] and in dying palliative care patients these drugs do not appear to hasten death. [55], [56]

Support for Families and Staff

Patients and families will need support in the form of effective communication and they may also need psychological support. This is often provided by ICU staff, particularly the nursing staff, with whom they may have spent significant time. Offers of additional psychological support should be made to patients and family members and accessed from the specialist palliative care team and from chaplaincy.

Palliative care continues as bereavement care after the patient dies. In practice, most bereavement support from the ICU is offered immediately after death or by external agencies. Needless to say, relatives need to be informed of the death in a sensitive manner; they also need to understand the cause of death. Features of a patient's illness and death can guide the identification of family members who may be at risk of complicated bereavement, alongside features of the bereaved person such as psychological morbidity, their relationship with the deceased and their social support. Referral to a local bereavement service or requesting permission to call the family doctor and arrange an appointment may be appropriate.

Bereavement surveys suggest ways we could improve the impact of relatives' deaths in the ICU, including skilled communication during critical illness and after death. Post-traumatic stress-related symptoms are more common among family members who felt the information given was incomplete. [31] These symptoms can translate subsequently to increased rates of anxiety and depression.

ICU staff suffer high levels of burnout and symptoms of post-traumatic stress disorder which has been demonstrated in studies before and after the COVID-19 pandemic. [57] ICU staff can reduce the negative impact of work through self-directed strategies such as exercise, mindfulness or social activities. However, there is also an organisational responsibility to provide psychological support which might include debriefing around deaths, a supportive environment and access to psychosocial resources. Unfortunately, the uptake of psychological support may be limited even where it is available, by stigma or a sense that the emotional impact is a normal part of the role. [58]

Organ Donation

The topic of organ donation and the ICU is more fully discussed in Chapter 113 . Involvement of the palliative care team may be helpful in providing additional emotional support to the family. There may also be an important role in managing signs of distress, especially during withdrawal of treatment in donation after circulatory death (DCD). In DCD the family may wish to be with the patient while treatment is withdrawn. This process is an opportunity for them to say goodbye and they may have specific wishes around prayer or cultural rituals that should be elicited and honoured as far as possible. Provision should be made for appropriate symptomatic drugs to be with the patient during DCD to treat signs of distress, as these will be unpleasant for the family, although they may not be experienced as discomfort by the patient.

Care Plans to Support End-of-Life Care in ICU

Individualised care plans and protocols have been recommended to improve the care of dying patients in the ICU. [59,60] Care plans should address appropriate assessment of symptoms, communication with family and patient if possible, psychological and spiritual support and support with practical issues such as open visiting and free car parking. [59] They act as a reminder to consider the appropriateness of each treatment in terms of the burden and benefit, and support the nursing staff in monitoring and maintaining comfort on an ongoing basis.

Stepping Down from the ICU at the End-of-Life

Some patients are able to transfer out of ICU for their last days, but this transition needs to be managed carefully to avoid additional family distress. The initial suggestion of stepping down from the ICU is another opportunity to utilise the palliative care team's expertise.

This transition is both a physical and emotional one for patients and families [61] who may feel that this step away from critical care in some way seals the fate of the patient. They will be concerned about losing the skilled staff and environment they know. Their anxiety may be compounded by the knowledge that there is not the same ratio of staff to patients outside the ICU. [62] Clear information about changes in the ward and treatments may help to reduce anxiety.

A member of the palliative care team can be helpful in providing continuity around this transition. If invited to meet the patient and family before transfer, they can begin to understand the specific needs of patient and family members including symptom control, emotional and spiritual issues.

The move should take place in a planned way with the family given as much forewarning as possible. Ideally, the patient should not be transferred at night or on weekends if this means there is less support available. Treatments and monitoring should not be discontinued immediately before the transfer, although some changes may be necessary if the ‘step-down’ ward does not usually care for patients with arterial lines or intravenous opioid infusions. The palliative care team can offer advice about the practicalities of continuing symptomatic medications after the move, and managing this transition seamlessly.

Conclusion

With advances in technology, there is likely to be an increase in trials of ICU treatment and a corresponding increase in transition to palliative care in the ICU. How this is managed will depend on local access to specialist palliative care resources and the focus of the ICU staff. Limitation of treatment, in whatever guise, is a difficult area and constitutes a significant part of clinical practice in the ICU. Cultural differences in approaches to information giving, autonomy and withdrawal of treatment will affect end-of-life care practices in the ICU. These cultural differences are seen across different parts of the world but can also exist within countries or even individual ICUs. These issues are immensely important to patients, their relatives and clinicians and deserve to be more openly discussed. Review of ICU deaths at mortality and morbidity meetings could include consideration of the quality of the patient’s end-of-life care and family support to promote learning and improve care for subsequent patients.

The determination of death in ICU

Ian Thomas and Stewart Moodie

Background

Death carries important societal, cultural, legal and medical implications making it imperative that its determination is accurate, reliable and secure. It is essential to have a clear distinction between life and death so that we are able to determine when loss of individual rights occurs, wills may be executed, efforts to preserve life can cease, organs and tissues can be donated, burial or cremation can be undertaken, and religious or social ceremonies that mark the end of life can be held.

The biological states of ‘alive’ and ‘dead’ are independent and cannot co-exist. Linking these two states is the process of dying during which there is progressive loss of cellular function. The end point of this process is death although identifying the exact point at which death has been reached will be dependent on societal consensus informed by scientific understanding and may vary between jurisdictions.

Historically, determining that the death of an individual had occurred merely required the passage of sufficient time for those somatic signs synonymous with death such as rigor mortis, putrefaction and decomposition, to appear. As biological understanding of the human being progressed it was recognised that death could be determined by confirming the simultaneous onset of continuous apnoea, pulselessness, unconsciousness and unresponsiveness. Representing the loss of circulation, respiratory and brain functions it was understood that the permanent cessation of any one of these three vital, interdependent functions was inevitably followed by the loss of the other two resulting in the death of an individual. Determining that an individual had died merely required the certainty that these three vital functions had ceased completely.

However, advances in medical technology including mechanical ventilation, cardiopulmonary resuscitation and extracorporeal membrane oxygenation led to the recognition that the circulation and respiratory systems could be sustained when they otherwise would permanently have ceased function. These technological advancements forever severed the interdependence of the three vital functions and an understanding that in patients with complete and permanent loss of brain function, their circulation and respiratory systems could be sustained almost indefinitely. The historical determination of death requiring the permanent cessation of the circulation, respiratory and brain functions was now inadequate. To reconcile this position, and in recognition that those key functions required for human existence originated in the brain, it was proposed that the permanent loss of brain function equated to the death of an individual, regardless of the technological support of the circulation and respiratory systems. This concept has been increasingly accepted and human death can be defined as 'the complete and permanent loss of brain function as defined by an unresponsive coma with loss of capacity for consciousness, brainstem reflexes and the ability to breathe independently'. [1] Previously often referred to as 'brain death' or 'brainstem death' this definition of death is a clear move away from one being based on an anatomical construct toward one based on the permanent loss of defined functions that can result from the permanent loss of the circulation to the brain following circulatory arrest, or a devastating primary brain injury. It further allows us to understand how death can be determined by circulatory criteria (DCC) or neurological criteria (DNC). Whenever there is a clinical suspicion that death has occurred, its determination should always occur using circulatory or neurological criteria irrespective of the potential for organ donation.

The Determination of Death by Circulatory Criteria

Following circulatory arrest there is rapid loss of blood circulation to the brain resulting in loss of brain activity and function. Permanent loss of the circulation therefore acts as a surrogate marker of loss of brain function. Since brain function cannot be restored without restoration of the circulation and perfusion, death can be determined with certainty once the possibility of the spontaneous return of the circulation has passed (autoresucitation), as long as no other interventions are undertaken that have the potential to restore the cerebral circulation after this point. In other words, loss of circulation inevitably leads to cessation of brain function, initially permanently (autoresuscitation is not possible) and then irreversibly (cerebral blood flow and subsequent perfusion cannot be restored by *any* intervention). The length of time following the onset of circulatory arrest before the possibility of autoresuscitation can be confidently said to have passed is unknown, and will be subject to local guidance although a minimum of 5 minutes has wide acceptance. [2-4] This is based on the longest period of time observed following circulatory arrest prior to the spontaneous resumption of cardiac activity, being 4 minutes 20 seconds. [5] Of note, this 5-minute period only applies following withdrawal of life-sustaining therapy and does not apply following cessation of cardiopulmonary resuscitation where spontaneous resumption of the circulation up to 10 minutes following cessation of resuscitative efforts has been reported. [6] Where invasive blood pressure monitoring has been undertaken the onset of circulatory arrest is defined as the onset of mechanical asystole as evidenced by the lack of a pulsatile waveform on a (functioning) arterial line trace. An isoelectric ECG is not required as long as electrical activity is not associated with any form of return of the circulation as demonstrated by the continual absence of pulsatile activity on the arterial line trace. Where invasive blood pressure monitoring is not in place, a continuous period of 5 minutes of electrical asystole is required to confirm the permanent loss of circulation. In the absence of either invasive blood pressure or ECG monitoring and where organ donation is not planned, permanent loss of the circulation is confirmed by clinical examination (absent heart sounds and/or absent central pulse) only.

The Determination of Death by Neurological Criteria

During the 1950s it was recognised that where brain function had been permanently lost, circulatory and respiratory function could be sustained utilising newly developed medical technologies. This clinical state was first described by Mollaret and Goulon in 1959 as ‘le coma depassé’ (a state beyond coma), characterised by unresponsive apnoeic coma, poikilothermia, brainstem areflexia and the absence of all activity on an electroencephalogram (EEG). [7] In 1968, an ad hoc committee of Harvard Medical School called for patients in an ‘irreversible coma’ to be confirmed dead by neurological criteria so allowing for mechanical ventilatory support to be withdrawn and, with appropriate permissions, organs to be retrieved for the purposes of transplantation. [8] This influential report led to neurological criteria for the determination of death being adopted in countries around the world, albeit with variability in aspects of the process.

International Variation in the Determination of Death by Neurological Criteria

In those countries where standards exist for the determination of death by neurological criteria, the general principles are the same. Variations exist in the preconditions that must be fulfilled, the precise process of cranial nerve examination, apnoea test requirements and the need to undertake ancillary investigations. International consensus is evolving through initiatives such as ‘The World Brain Death Project’. [1] This evidence-based consensus allows those countries without professional guidance to adopt consistent standards and increase general public and professional confidence in accepting the determination of death by neurological criteria.

General principles for the determination of death by neurological criteria

The determination of death by neurological criteria should always be undertaken where it is clinically suspected, irrespective of the potential for organ donation. The majority of countries have followed the lead of the United States, United Kingdom, Australia, New Zealand and Canada specifying that a clinical examination is the primary process for the determination of death by neurological criteria. Three sequential but interdependent steps form the diagnostic criteria: fulfilment of essential preconditions, exclusion of reversible causes of coma and apnoea, and the clinical confirmation of unresponsive coma, brainstem areflexia and apnoea. Whilst the third step, the clinical examination, demonstrates the absence of brainstem function, it is the first two that determine permanency and require a greater degree of expertise to interpret.

Preconditions

The patient's comatose condition and apnoea *must* be due to a devastating brain injury of known aetiology. It is vital that a structural cause of the coma is established as a loss of brain stem reflexes can be found in other conditions including after a drug overdose.[9,10] This is established through the clinical history and neuroradiological confirmation of a devastating brain injury. Permanency requires an adequate period of observation following the loss of the last brainstem reflex, prior to clinical testing. In a devastating traumatic brain injury or intracranial haemorrhage, this period of time can be as short as 4 hours, although it varies between countries. Generally, where the nature of the injury is hypoxic-ischaemic encephalopathy this is extended to 24 hours, although again, there is variation between countries.

Exclusion of Potentially Reversible Causes

Prior to undertaking clinical testing to demonstrate permanent coma, brainstem areflexia and apnoea, it is essential that all potentially reversible causes have been excluded (Table 14.1). The confounding effects of hypothermia, depressant drugs and severe electrolyte abnormalities are all consistently cited in clinical guidelines, but the thresholds vary between them.[11] If any of these potentially reversible causes are found to exist, either correction of the variable must be undertaken or more time allowed such that it can be certain that it is not contributing to the coma. If this cannot be done or time is a critical factor, an ancillary test will be required to confirm the determination of death by neurological criteria.

Table 14.1

Drug Effects

The effects of sedative and paralysing drugs must be excluded as a cause of, or be contributing to, the patient’s coma. Sufficient time must be allowed for sedative drugs to be metabolised and excreted; five half-lives in the presence of normal hepatic and renal function are usually considered appropriate. However, the presence of hypothermia as well as hepatic or renal dysfunction brings significant alterations in drug metabolism such that there may be uncertainty as to whether residual levels of sedatives are contributing to the patient’s coma. The plasma concentration of some sedatives can be measured, but clinical interpretation of the level can be difficult because of the unpredictable effects on consciousness of a given drug concentration in a critically ill brain-injured patient. Administration of specific antagonists to exclude opioid or benzodiazepine effects can be considered. Residual pharmacological paralysis should be excluded by ‘train-of-four’ stimulation to confirm the absence of neuromuscular blockade.

Hypothermia

Although brainstem reflexes are likely to be absent only if body temperature falls below 28°C, temperatures between 32°C and 34°C have occasionally been associated with impaired consciousness. Most guidelines recommend that core temperature should be at or near normal (>34°C) at the time of the clinical examination.

Metabolic, Electrolyte and Endocrine Disturbance

All guidelines require that there should be no evidence of severe metabolic, electrolyte or endocrine disturbance, but ‘severe’ is rarely defined. Diabetes insipidus-related hypernatraemia is a common consequence of loss of brain function and should be corrected to within a specified target range prior to undertaking clinical testing. Acute or decompensated liver failure can cause coma and delay the metabolism of sedative drugs so should be excluded as a reversible cause. Blood glucose concentration should be normalised prior to and during the clinical examination(s). Several endocrine abnormalities can be associated with impaired consciousness or present as acute coma, but are rare and unlikely to co-exist in the presence of known primary intracranial pathology. Examples include myxoedema coma or an Addisonian crisis. Hormone assays are generally only recommended if there is any clinical suspicion of endocrine disturbance.

Cardiorespiratory Disturbances

Progressive ischaemia of the brainstem leads to profound sympathetic output that can be clinically manifest as intense circulatory and respiratory disturbance. Oxygen saturation should be maintained greater than 95% and a systolic blood pressure above 100 mm Hg systolic or a mean arterial pressure above 60 mm Hg should be established before, and maintained throughout, the clinical testing.

Cervical-Level Cord Injury

A spinal cord injury within the cervical region will prevent a peripheral motor response to a central stimulus. Injury to the upper levels of the cervical spinal cord will prevent spontaneous ventilation and therefore the apnoea test cannot be undertaken. Any clinical or radiological suspicion of a cervical spine injury will require an ancillary test in addition to clinical testing to allow the determination of death by neurological criteria.

Clinical Examination

The clinical examination is designed to confirm the presence of an unresponsive coma, brainstem areflexia and apnoea. In most countries, if all the preconditions are met then a completed clinical examination determines that death by neurological criteria has occurred. In some countries, local protocols will also require an ancillary test to be performed. To complete the clinical examination, at least one eye should be examinable for the pupillary, corneal and vestibular-ocular reflexes, and one ear examinable for the vestibular-ocular reflex. If any of the preconditions are not met or parts of the examination are not able to be performed, then the examination should be performed to the fullest extent possible. Following that, an ancillary test should be performed. If clinical testing confirms the presence of any brainstem function, then this precludes the determination of death by neurological criteria. The examination should cease at that point as death has not occurred.

Unresponsive Coma

Any response within the cranial nerve distribution to a centrally administered noxious stimulus (usually the application of supraorbital pressure) precludes the determination of death by neurological criteria. Some countries also require a lack of response to a noxious stimulus applied peripherally to ascertain an unresponsive coma.[1,3,4] Care must be taken in evaluating any peripheral movement to stimulation, as spinal reflexes may occur. Spinal reflexes do not involve the brainstem and can occur in up to 50% of patients after the determination of death by neurological criteria.[12] They are often seen in response to a relatively minor peripheral stimulus. They can be complex in nature and disturbing when observed by family members and staff. It is important that these movements are acknowledged, and their origin explained. It is recommended that an ancillary test should be performed if there is any doubt about whether movements are spinal in origin.

Cranial Nerve Examination

The cranial nerve examination is common to all guidelines for the determination of death by neurological criteria. The assessment includes an examination of cranial nerves II, III, V, VII, IX and X (Table 14.2).

Table 14.2

Components of the cranial nerve examination for the determination of death by neurological criteria

TEST	CRANIAL NERVES INVOLVED	NOTES
Pupillary light reflex	II and III	Absent pupillary response to sharp changes in the intensity of incident light. Pupils do not need to be maximally dilated or equal, simply unresponsive
Corneal reflex	V and VII	No blinking in response to a sterile gauze touched onto the cornea (not sclera)
Response to adequate stimulation in the trigeminal areas	V and VII	No facial or limb movement to firm pressure over the supraorbital area or temporomandibular joint
Vestibular-ocular reflex	III, IV, VI, VIII	Clear access to the tympanic membrane must be confirmed by direct inspection prior to testing. Head at 30 degrees to the horizontal unless contraindicated by an unstable cervical spine injury. No eye movements during or following slow injection of 50 mL ice-cold water over 1 min into each external auditory meatus

TEST	CRANIAL NERVES INVOLVED	NOTES
Oculo-cephalic reflex	III, VI, VIII	Not required in all jurisdictions. Eyes remain in mid-position during brisk turning of the head from side to side (‘doll’s eyes’). Only tested if cervical spine integrity ensured
Gag reflex	IX, X	No response to stimulation (under direct vision) of the posterior pharynx
Cough reflex	X	No cough response to deep tracheal suctioning stimulating the carina
Apnoea test		Only performed if previous cranial nerve examination has confirmed the absence of function. Absence of respiratory effort observed despite an adequate respiratory acidaemia. $PaCO_2$ must rise to a specified target (guidelines vary – most require that $PaCO_2$ should be greater than 8.0 kPa or 60 mmHg or have increased more than 2.5 kPa or 20 mmHg above a chronic baseline with a pH of <7.30). Cardiovascular stability maintained during the test (systolic blood pressure >100 mm Hg or MAP >60 mm Hg)

Apnoea Test

Testing for apnoea is fundamental to the determination of death by neurological criteria, although endpoints differ.[11] Whilst the overall aim is to produce an acidaemic respiratory stimulus, fewer than 60% of jurisdictions specify a $PaCO_2$ target for the end point of the apnoea test. The apnoea test should be the last of the clinical tests undertaken to confirm brainstem areflexia and only after areflexia has been confirmed up to that point. Profound hypoxaemia, excessive hypercarbia or significant changes in mean arterial blood pressure should be avoided whilst the apnoea test is performed. Many jurisdictions provide structured guidance on how to perform the apnoea test, including specific targets for the $PaCO_2$ and pH to ensure that an adequate threshold to stimulate spontaneous ventilation has been reached.

The patient should always be disconnected from the ventilator during the apnoea test because autocycling can incorrectly suggest the presence of spontaneous ventilation. Positive end-expiratory pressure (PEEP) can be maintained through a self-inflating bag with the valve adjusted to maintain oxygenation and limit the development of atelectasis. Apnoea is confirmed following visual inspection for at least 5 minutes to confirm the absence of spontaneous ventilation and after thresholds for the $PaCO_2$ and pH have been reached. Recruitment breaths may then be performed via a manual breathing circuit. The ventilator is then reconnected, and the minute volume is adjusted to allow a gradual return of arterial blood gases to pre-test levels. No defined level of a minimum oxygen saturation level exists as to when the apnoea test should be stopped and techniques to limit desaturation such as the administration of 100% oxygen before and during the test, the administration of PEEP and recruitment manoeuvres should be considered to limit its occurrence. Where the apnoea test cannot be completed due to cardiovascular or respiratory instability the clinical testing should be completed to as full an extent as possible and an ancillary test performed to determine death by neurological criteria.

Repetition and Observation of Clinical Tests

Two clinical examinations are required to determine death by neurological criteria in many countries, although there is an increasing trend towards the requirement for only a single examination. Where two examinations are required, there is often no specified time interval between them. In the United Kingdom, the second examination can be undertaken as soon as arterial blood gases have returned to baseline after the first apnoea test. The legal time for determination of death is usually on completion of the first clinical test but in Australia and New Zealand, the time of death is that of the completion of the second clinical test. The opportunity to observe the clinical examination can assist families to understand that their family member has died. [13] If families accept the offer, there should be a careful explanation prior to the clinical testing with a specific person identified to support the family.

The number of doctors required to determine death by neurological criteria also varies. In most jurisdictions a single doctor is sufficient, but in the United Kingdom, Australia, New Zealand and some parts of the United States at least two medical practitioners are required. The base specialty and seniority of the doctors determining death by neurological criteria are stipulated in some countries while, in others, relevant competencies are defined. [11] To avoid any conflict of interest, the determination of death by neurological criteria should not be undertaken by a clinician involved in any aspect of organ transplantation.

Ancillary tests

Ancillary tests should be performed when a full clinical examination cannot be performed or when potentially reversible causes cannot be excluded. In some countries, they are also required in addition to a full clinical examination. [14], [15] Ancillary investigations can be considered as either an assessment of brain perfusion or electrophysiological activity. [16]

Assessment of Cerebral Perfusion

Absence of cerebral perfusion is widely accepted to be consistent with the determination of death by neurological criteria. Methods to confirm the absence of cerebral perfusion are less affected by confounding factors such as residual sedation, metabolic disturbance or hypothermia than electrophysiological methods, and are preferred.

Cerebral Angiography

Four-vessel digital subtraction cerebral angiography (DSA) is the gold-standard ancillary test for the determination of death by neurological criteria in some countries. [14] Following bilateral injection of contrast into vertebral and carotid arteries, the absence of flow beyond the foramen magnum in the posterior circulation and beyond the petrosal portion of the carotid artery in the anterior circulation is accepted to confirm the determination of death by neurological criteria.

Non-invasive vascular techniques such as computed tomography (CT) and cerebral angiography (CTA) are increasingly employed with national guidance detailing the protocol and reporting framework required to establish the presence or absence of intracranial blood flow now available. [17] CTA has a high sensitivity for the determination of death by neurological criteria in individuals who fulfil the clinical diagnostic criteria. A significant proportion of patients meeting clinical criteria for the determination of death by neurological criteria retain some evidence of contrast in the proximal intracranial arteries with all angiographic techniques. [18] False-negative results can occur, particularly after decompressive craniectomy and in the presence of cerebrospinal fluid drains. Systolic blood pressure should be maintained above 100 mm Hg or MAP > 60 mm Hg whilst a CTA is being performed. [14]

Perfusion Imaging

Contrast-enhanced CT cerebral perfusion techniques are widely available, although there is little evidence of advantages over CTA. Positron emission tomography measures the regional cerebral metabolic rate for glucose in addition to regional blood flow. Nuclear imaging techniques are also able to confirm absent cerebral perfusion; an ‘empty skull’ appearance in which no intracranial contrast is visible. [14]

Transcranial Doppler Ultrasonography

Transcranial Doppler (TCD) is a non-invasive bedside investigation that can be used as an ancillary test. [19] When intracranial pressure exceeds mean arterial blood pressure, TCD assessment of blood flow velocity in basal cerebral vessels reveals systolic spikes with reversal of diastolic flow. The absence of a TCD waveform should never be taken as confirmation of absent cerebral blood flow because at least 10% of patients have no acoustic bone window. TCD examination has high sensitivity (86%) and specificity (98%) for the determination of death by neurological criteria when compared to clinical examination, with very few false-positive cases reported in the literature. [14] There is significant operator dependence, and previous surgery or open ventricular drains make TCD waveform interpretation difficult.

Electrophysiology

Electroencephalography (EEG) remains widely used in the determination of death by neurological criteria despite substantial disadvantages and a requirement for specialist interpretation. The absence of cortical electrical activity during high-sensitivity recordings from 16 or 18 channels over 30 minutes is often taken as determining death by neurological criteria. However, an isoelectric cortical EEG does not exclude activity in the brainstem or other deep structures, and electrical activity in some cortical cells does not invalidate a diagnosis of death if the absence of brainstem function has been demonstrated. [14] EEG examination is a mandatory part of the determination of death by neurological criteria in many European countries and is strongly recommended in some states in the United States where loss of whole brain function must be confirmed. However, EEG is affected by hypothermia and sedation, and this has led to calls that an EEG should no longer be used as an ancillary test in the determination of death by neurological criteria. [16]

False-Positive Clinical Tests

There are no published reports of recovery of neurological function after the determination of death by neurological criteria when all the criteria required to confirm death have been accurately followed. Case reports exist highlighting situations or conditions that may mimic the state and lead to erroneous conclusions if unrecognised.[9,10,20] Such diagnostic errors invariably involve failure to identify preconditions and exclude reversible factors contributing to the clinical state:

- The effects of high-dose sedative or opioid infusions may persist for several days after discontinuation, particularly in the presence of hypothermia. In one report, a very high cumulative dose of fentanyl in a patient with renal and hepatic impairment who had been treated with therapeutic hypothermia after a cardiac arrest may not have been excluded as contributing to the coma.[21]
- Other conditions that have been reported to mimic brainstem areflexia include baclofen and valproic acid overdose, therapeutic barbiturate coma, organophosphate intoxication and some neurological conditions such as fulminant Guillain-Barré syndrome or Miller-Fisher variant.[20] Importantly, there will be the absence of evidence of structural brain injury in these cases so the preconditions for undertaking clinical testing are not met.[22]

The Determination of Death by Neurological Criteria in Special Circumstances

Extracorporeal Membrane Oxygenation

Patients receiving extracorporeal membrane oxygenation (ECMO) can undergo clinical testing to determine death by neurological criteria. Drug sequestration in the extracorporeal circuit and difficulties in undertaking the apnoea test provide challenges but published guidance exists that detail how neurological testing should be undertaken in the presence of ECMO.[23]

The determination of death by neurological criteria in children

The United Kingdom, United States of America, Canada, Australia and New Zealand have similar guidance for the determination of death by neurological criteria in neonates and children. Clinical determination in neonates (<30 days) can be more problematic than in adults because of difficulties performing the clinical examination and the relative immaturity of some brainstem reflexes.[24] The majority of countries have separate guidelines for the determination of death by neurological criteria in infants and children, but clinical examination remains paramount in all.[25] In those over 1 month of age, the general criteria are the same as for adults but the observation period is often longer after the loss of the last brainstem reflex and ancillary investigations are required in some countries. A higher $PaCO_2$ is also recommended during the apnoea test in some countries. As in adults, the clinical confirmation must be undertaken by two competent physicians but, in the case of children, one should be a paediatrician and the other not directly involved in the child's clinical care. Two clinical examinations, separated by an observation period that varies with age, are required to determine death by neurological criteria in children in most countries.[25]

Sepsis and septic shock

Jonathan Edward Millar and Manu Shankar-Hari

Introduction

Sepsis is a medical diagnosis, identified in patients using clinical (including history, and physiological derangements on examination) and laboratory parameters. Although sepsis commonly results from either bacterial or viral infection (a recent example being COVID-19), fungal, protozoal or parasitic infections or combinations of pathogens (such as bacterial co-infections with influenza, [1] bacterial co-infections with malaria [2]) could result in sepsis. Despite decades of research, with a focus on fast treatment and modulating the host responses to infection, there is no single immunomodulatory or other treatment for sepsis. Thus currently, management of sepsis remains largely focused on quality improvement approaches for prompt suspicion, timely administration of empiric antimicrobial therapy, fluid resuscitation, source control and supporting failing vital organ systems.

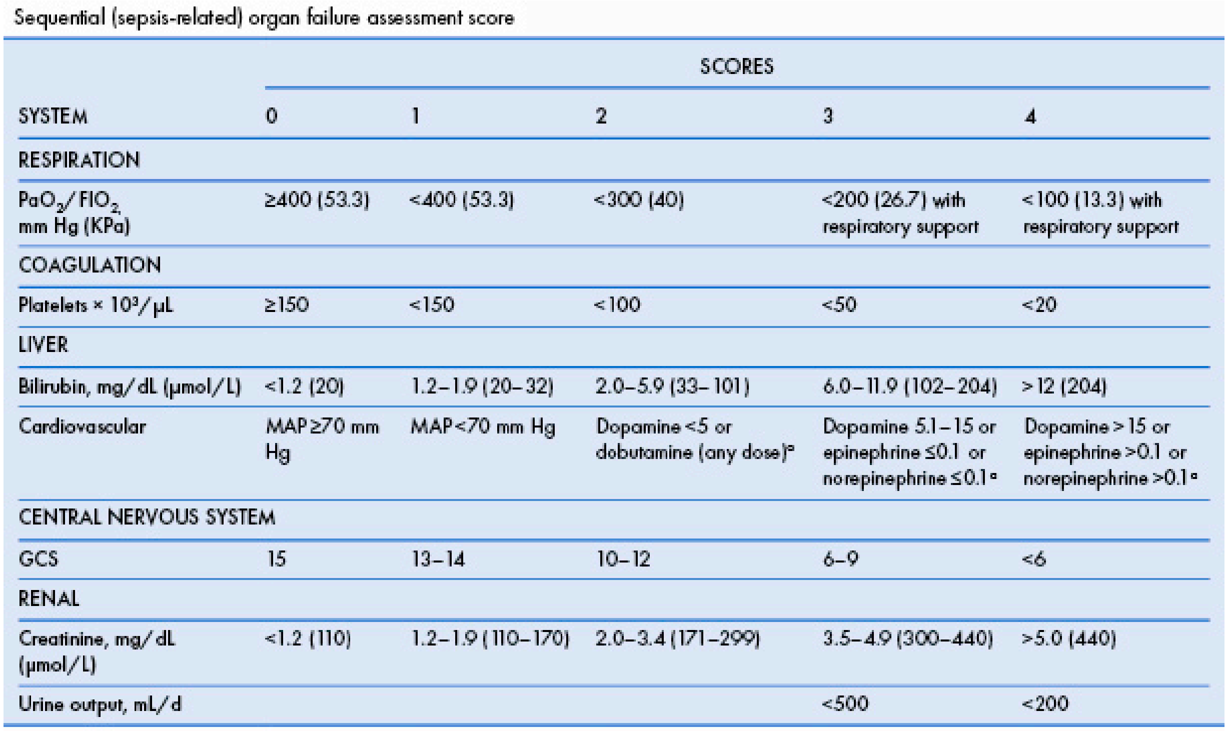
Sepsis-3 Definitions and Clinical Criteria

The current definitions of sepsis and septic shock are based on the last revision in 2016, referred to as Sepsis-3. [3-5] In Sepsis-3, the definition refers to the description of the illness concept and criteria refer to the clinical variables used to identify a patient meeting the illness concept.

Sepsis

Sepsis is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection. [3] The clinical criteria for sepsis are represented by an increase in the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) [6] a score of 2 points or more with clinically suspected or proven infection (Table 15.1). With this operationalisation, the expected in-hospital mortality for a patient with sepsis is likely to be greater than 10%. [3], [4] It is important to note that the current SOFA score has numerous limitations, including a lack of representation for the immune and gastrointestinal organ systems and is in the process of being updated. [7]

Table 15.1



Sequential (sepsis-related) organ failure assessment score

	SCORES				
SYSTEM	0	1	2	3	4
RESPIRATION					
PaO_2/FIO_2, mm Hg (KPa)	≥400 (53.3)	<400 (53.3)	<300 (40)	<200 (26.7) with respiratory support	<100 (13.3) with respiratory support
COAGULATION					
Platelets $\times 10^3$/µL	≥150	<150	<100	<50	<20
LIVER					
Bilirubin, mg/dL (µmol/L)	<1.2 (20)	1.2–1.9 (20–32)	2.0–5.9 (33–101)	6.0–11.9 (102–204)	>12 (204)
Cardiovascular	MAP ≥70 mm Hg	MAP <70 mm Hg	Dopamine <5 or dobutamine (any dose)[a]	Dopamine 5.1–15 or epinephrine ≤0.1 or norepinephrine ≤0.1[a]	Dopamine >15 or epinephrine >0.1 or norepinephrine >0.1[a]
CENTRAL NERVOUS SYSTEM					
GCS	15	13–14	10–12	6–9	<6
RENAL					
Creatinine, mg/dL (µmol/L)	<1.2 (110)	1.2–1.9 (110–170)	2.0–3.4 (171–299)	3.5–4.9 (300–440)	>5.0 (440)
Urine output, mL/d				<500	<200

[a] Catecholamine doses are given as µg/kg/min for at least 1 hour.

FIO_2 , Fraction of inspired oxygen; *GCS* , Glasgow Coma Score; *MAP* , mean arterial pressure; *PaO_2* , partial pressure of oxygen.

From Singer M, Deutschman CS, Seymour CW, et al. The third international consensus definitions for sepsis and septic shock (sepsis-3). *JAMA* . 2016;315:801–810.

Septic Shock

Septic shock is defined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone. The clinical criteria for septic shock are represented by a vasopressor requirement to maintain a mean arterial pressure of 65 mm Hg or greater and a serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia. Hypotension requiring vasopressor therapy after resuscitation is framed as a profound circulatory abnormality. Blood lactate levels are conceptualised as the surrogate for cellular and metabolic abnormalities. With this operationalisation, the expected in-hospital mortality for a patient with septic shock is likely to be greater than 40%. [5]

qSOFA

The Sepsis-3 consensus definitions did not redefine the term ‘infection’. Instead, Sepsis-3 generated a set of clinical criteria that could be used to rapidly identify amongst the acutely unwell adult patients, those with suspected or confirmed infection who are more likely to have poor outcomes typical of sepsis. These criteria are referred to as the quick SOFA (qSOFA) score, which consists of three rapidly measurable clinical variables: respiratory rate, altered mentation and systolic blood pressure. Adult patients with suspected or confirmed infection with at least two of the following clinical criteria: respiratory rate of 22/min or greater, altered mentation or systolic blood pressure of 100 mm Hg or less; are more likely to have poor outcomes typical of sepsis. Of note, the qSOFA score is often misinterpreted as a screening tool. Failure to meet ≥2 qSOFA criteria should not lead to a deferral of investigation or treatment of suspected infection or to a delay in any other aspect of sepsis management, including formal assessment of organ dysfunction if clinically indicated.

Epidemiology

In 2017, sepsis was recognised as a global health priority, by the World Health Assembly. [8] In many countries, the incidence of sepsis now exceeds that of acute myocardial infarction. [9] Whilst understanding the true global epidemiology of sepsis remains a challenge, the following section highlighting the epidemiology gives an overview of the problem.

Incidence and Short-Term Mortality

Rudd and colleagues reported the global incidence of and mortality from sepsis using extrapolations from the Global Burden of Diseases, Injuries, and Risk Factors Study (GBD) 2017 estimates for causes of death and diseases. [10] Based on these extrapolations, the incidence of sepsis worldwide in 2017 was 48.9 (95% uncertainty interval (UI) 38.9–62.9) million cases. The corresponding global age-standardised incidence in 2017 was 677.5 (95% UI 5357–8761) cases per 100,000 population. [10] The corresponding hospital-treated incidence and critical care treated-incidence are estimated at 189 (95% confidence intervals (CI) 133–267) hospital-treated sepsis cases per 100,000 person-years and 58 [95% CI 42–81] per 100,000 person-years, respectively. [11] Sepsis incidence patterns have two peaks, one in early childhood (neonates/infants) and a second in older adults (~70 years or older). Sepsis is more common in lower socio-demographic index settings. [10] The extrapolated global estimates for deaths associated with sepsis was 11.0 million (95% UI 10.1–12.0). [10] Sepsis affects all ages. The corresponding hospital mortality in hospital-treated sepsis and critical care-treated sepsis cases are estimated at 26.7% (95% CI 22.9–30.7) and 41.9% (95% CI 36.2, 47.7) respectively. [11] However, the true burden is not known. Most cases occur in low and middle-income countries, for which there are few data, high rates of antimicrobial resistance, and higher case fatality rates. [12-14]

Attributable Fraction and Sepsis

Conceptually, the attributable fraction represents the proportion of deaths or other adverse events that can be attributed to sepsis. The clinical value being that it provides an estimate of the mortality reduction that would occur in a population with sepsis if the clinical management would eliminate the risk due to sepsis. This concept has also a role in trial design.

The magnitude of attributable fraction for adverse events in patients with sepsis varies depending on the comparator population used in estimations. For mortality, it ranges between 15% (95% CI 14%–16%) with propensity-matched ICU-non-sepsis controls and 93% (95% CI 92%–93%) compared with age-sex-matched general population controls. [15-17] Stated differently, not all adverse outcomes in patients with sepsis are likely to be neither caused by sepsis nor completely preventable or reversible with treatments.

Long-term Outcomes Following Sepsis

Patients who survive sepsis have long-term adverse health such as a higher risk of rehospitalisation, [18] and a greater need for managing worsening comorbidities (e.g. new or accelerated cardiovascular disease, [19] , [20] new or worsening pre-existing cognitive impairment [21] , [22]) for years following index sepsis episode. Mortality in the first year following index sepsis episode in a sepsis survivor population is estimated at 15%, [23-25] much higher than age- and sex-matched controls. Conceptual reviews on the longer-term outcomes following sepsis highlight a complex illness with potentially modifiable clinical risk, and biological mechanisms, [26] , [27] with some similarities to post-acute sequalae observations in survivors of COVID-19. [28] This constellation of post-acute long-term sequelae reported in sepsis survivors consisting of immune, metabolic, neurocognitive, psychiatric, physical derangements resulting in severely worsened health-related quality of life, [23] , [24] , [29] rehospitalisation and long-term mortality is referred to as *post-sepsis syndrome.* [27] , [30]

Pathobiology

Definition of Dysregulated Immune Responses

Recently, dysregulated host immune responses in sepsis were defined as pathologic disruption and/or alteration in homeostasis of the immune-driven resistance, disease tolerance and resolution mechanisms occurring concurrently. [31] Resistance refers to effector mechanisms that reduce pathogen burden once the infection is established through detection, neutralisation, killing or expulsion of microorganisms and production of inflammatory mediators (also referred to as inflammatory cost to the host). Disease tolerance refers to an evolutionary conserved defence strategy that limits the severity of infectious diseases, without directly affecting pathogen burden. Resolution is conceptualised as a tightly regulated and active biological process that restores tissue homeostasis following inflammation. Clinical equivalents of the inflammatory costs to the host are the adverse outcomes in patients with sepsis.

Overview of Dysregulated Immune Responses

A detailed description of the dysregulated immune responses is beyond the scope of this chapter. Please refer to the following reviews on state-of-the-art immunobiology, [32] how to profile the immune system in patients with sepsis at the bedside, [33] and the need to completely rethink sepsis immunobiology for successful immunomodulation in the future. [21] What follows is a brief outline of host responses described in patients with sepsis and or in animal models of sepsis. [34]

Sepsis is characterised by concurrent *hyperinflammation* and *immunosuppression* , two normally opposing reactions that involve distinct immune cell types and organ systems. These maladaptive responses are typically present to variable degrees in an individual, over the natural history of sepsis. These responses are triggered by a sustained engagement of pattern-recognition receptors (PRRs) expressed by innate immune cells, pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs). Among critically ill patients with sepsis who fail to recover after early therapeutic measures, a chronic critical illness state may develop called ‘persistent inflammation, immunosuppression and catabolism syndrome’. [35]

Hyperinflammation is caused by the uncontrolled activity of pro-inflammatory effector mechanisms, involving activated leukocytes and endothelial cells with concomitant dysregulated production of oxygen and/or nitrogen radicals, cytokines, and activation of the complement and coagulation systems. Whilst the activation of these mechanisms is part of innate immune responses to infection (i.e. inflammatory, and protective trade-off responses), their uncontrolled activity can cause collateral damage and play a key role in the pathogenesis of sepsis. [32]

Pro-inflammatory cytokines such as tumour necrosis factor (TNF) and interleukin (IL)-1β are considered to play an important role in tissue injury, and their unrestrained activity contributes to excessive inflammation during sepsis. [36] Additionally, activated neutrophils release reactive oxygen species and proteases that amplify inflammation and coagulopathy [37] in sepsis. The proteases can form part of neutrophil extracellular traps (NETs), which are extracellular fibre networks containing histones and DNA released by activated neutrophils. [38,39] Whilst NETs are important for host defence, their excessive formation can cause vascular and tissue damage, and activation of the coagulation system, contributing to organ dysfunction. Neutrophils also display reduced migration to chemoattractant, lower intracellular myeloperoxidase and lactoferrin content, and reduced oxidative burst capacity, all indicating an immune-compromised neutrophil phenotype in sepsis. [40] Recent work using single-cell multi-omic approaches has shown that dysfunctional neutrophils and emergency granulopoiesis drive a maladaptive response in a subset of patients with sepsis with poor outcomes previously identified by whole blood transcriptomics (sepsis response signature, SRS1). [41] This involved specific immunosuppressive *IL1R2+* immature neutrophil populations with similar expression patterns to MS1 cells, and epigenetic and transcriptomic signatures of emergency granulopoiesis in circulating haematopoietic stem cells, suggesting an innate immune and haematopoietic axis underlying the maladaptive immune response to infection during sepsis. [41]

The complement and coagulation systems are crucial pro-inflammatory pathways involved in the pathogenesis of sepsis, that can worsen hyperinflammation. [42,43] Whilst complement activation marks microbial intruders for lysis and opsonisation, uncontrolled complement activation can injure tissues. Complement activation also releases C3a and C5a, which are powerful pro-inflammatory molecules that recruit and activate immune cells and platelets, regulate vascular flow, increase vascular permeability, and promote leukocyte vascular adhesion and mobility. Complement inhibition attenuates systemic inflammation and coagulation, and improves outcomes in several preclinical sepsis models, [42] and in patients with sepsis and COVID-19. [44, 45]

Coagulation system imbalances during sepsis include strong procoagulant activity with concurrent impairment of endogenous anticoagulant mechanisms. [43] This can lead to disseminated intravascular coagulation, which clinically presents as microvascular thrombosis combined with haemorrhage due to consumptive coagulopathy. The main driver of coagulation activation is tissue factor, which can be produced by tissue-resident macrophages and circulating monocytes upon stimulation by PAMPs, cytokines and complement factors. [46] Tissue factor is also detected in *microvesicles* in the circulation of patients with sepsis, originating from several cellular sources. The blockade of tissue factor strongly reduced coagulation activation in humans and non-human primates during experimental endotoxemia and bacteraemia. Pore-forming protein gasdermin D formed during sepsis contributes to the release of pro-inflammatory cytokines such as IL-1α, execution of PANoptosis, [47, 48] and links pro-inflammatory cell death to excess coagulation [49] in sepsis.

The unrestricted activation of immunoregulatory mechanisms during infection can result in sustained immune suppression, involving different cell types. [50, 51] Sepsis is associated with widespread mononuclear leukocyte programmed cell death [52] , reducing the number of T-cells (helper (CD4+), and cytotoxic (CD8+)), B-cells, natural killer cells and dendritic cells. Whilst the accelerated loss of lymphocytes results in lymphopenia, [53] the greater loss of memory B-cell [54] and T-cell subsets [55] contribute to observed immunosuppression in sepsis. [33, 56, 57] These observations highlight drugs with lymphocyte homeostatic proliferation effects such as recombinant interleukin-7 [58] and vaccination as a strategy to reduce adverse outcomes in sepsis survivors. Checkpoint regulators, which act as a 'second signal' to license adaptive immune responses to specific antigens, have received much attention in the context of sepsis pathophysiology, [59, 60] in part because of their recognised importance in oncology (see below), and evidence for safety in early phase clinical trials. [61, 62] Patients with sepsis exhibit increased expression of the checkpoint inhibitor programmed death-1 (PD-1) on T-cells, monocytes, and granulocytes, and elevated T-cell PD-1 levels are associated with impaired T-cell function, a higher frequency of nosocomial infections and increased mortality in patients with sepsis.[60] Monocytes and macrophages from patients with sepsis display lower surface levels of human leukocyte antigen (HLA)-DR, indicative of a reduced capacity for antigen presentation and considered a key feature of sepsis-induced immune suppression. These cell types undergo transcriptional and metabolic reprogramming in sepsis, leading to an impaired capacity to produce a subset of pro-inflammatory cytokines upon re-stimulation by bacterial PAMPs, such as lipopolysaccharide, a phenomenon that has been called *endotoxin tolerance*. The functional change in monocytes and macrophages in sepsis is caused, at least in part, by epigenetic modifications, such as altered DNA methylation and histone modifications,[63] and involves a reduced capacity to activate the master transcriptional regulator of inflammation nuclear factor-κB.[50], [51] Notably, this 'tolerant' state is not universally present at different body sites: evidence exists for tissue specificity, where for example macrophages in the liver and lung showed a primed rather than a tolerant phenotype upon re-stimulation.[63], [64] A relative increase in the number of regulatory T cells and myeloid-derived suppressor cells further contributes to immunosuppression in sepsis. CD14+ monocyte subset named MS1 in patients with sepsis, is characterised by high expression of *RETN*, *ALOX5AP*, and *IL1R2*, which was associated with immunosuppression.[65] MS1 cells likely represent monocytic myeloid-derived suppressor cells, and in co-culture systems suppressed T-cell proliferation and inhibited endothelial cell activation, indicative of their immune suppressive features.

Mechanisms of Organ Dysfunction in Sepsis

The exact mechanisms of organ dysfunction in sepsis are unclear. Currently proposed mechanisms for organ dysfunction are either impaired oxygen handling by cells within organs (i.e. cellular dysoxia), or cellular metabolic reprogramming as protective survival responses to the infection itself or to the dysregulated host immune responses (i.e. disease tolerance mechanisms). These hypotheses are supported by observations such as minimal necrosis to organ cells, altered mitochondrial structure, altered mitochondrial function and abnormalities in the endoplasmic reticulum seen in animal models of sepsis as well as in post-mortem studies in patients who die with a diagnosis of sepsis. [66-68]

Mechanisms of Raised Lactate in Sepsis and Septic Shock

Despite decades of research, there is much debate as to the mechanisms for raised lactate in patients with sepsis and septic shock, [69] including an ongoing debate on the relationship to inflammation. [70] Even at clinical presentation (i.e. before resuscitation has commenced), although the raised lactate could be multifactorial, the most likely mechanism would be impaired oxygen delivery to tissues and anaerobic glycolysis. This was the premise of the original early goal-directed therapy trial. [71] Other mechanisms of raised lactate at any stage of sepsis would be β2-receptor stimulation from endogenous/exogenous catecholamines, impaired tissue oxygen extraction (mitochondrial dysfunction with or without microcirculatory dysfunction), liver dysfunction, cardiac dysfunction, pyruvate dehydrogenase complex inhibition [72] and thiamine deficiency. [73] After initial resuscitation, there is ongoing debate on the dominant mechanisms compensating the acidosis with raised lactate. Gattinoni and colleagues reason that the ability to maintain a normal pH despite raised lactate is more closely related to renal rather than respiratory compensatory mechanisms. [74]

Clinical management

Overview

The basic tenets of clinical management are covered within the Surviving Sepsis Campaign (SSC) guidelines for adult patients with sepsis or septic shock in hospital settings. [75] Recommendations from SSC guidelines should not be used to override clinical decisions made on individual patient's history, physical examination, and laboratory variables. Management of sepsis involves maintaining a high index of suspicion when evaluating any acutely unwell patient. Rapid management of suspected sources of infection consists of initiating appropriate antimicrobial therapy and effective source control measures (such as drainage of collections and laparotomy). Other supportive measures include resuscitation, and individual organ support (Table 15.2).

Table 15.2

Surviving Sepsis Campaign (SSC) Guidelines

The following section provides a summary of the International Guidelines for Management of Sepsis and Septic Shock 2021 75 that guide the bedside management of patients with sepsis.

Overview of SSC Guideline Methodology

The SSC guidelines use the GRADE methodology to assess the quality of evidence, followed by an Evidence-to-Decision framework that incorporates patient values, resources and cost, equity, acceptability and feasibility to generate recommendations to generate either *best practice statements* (BPSs) or *strong/weak recommendations* . The strong recommendations have high confidence in the desirable effects of a particular treatment, weak recommendations indicate that desirable effects likely outweigh undesirable effects and BPSs are ungraded strong recommendations where evidence is difficult to summarise or assess according to GRADE methodology.[75], [76] Based on the above summarised methodology, the 2021 SSC guidelines have 93 statements consisting of 15 (16%) strong recommendations, 54 (58%) weak recommendations, 15 (16%) BPSs and 9 (10%) no recommendation statements (Table 15.2). Among the strong recommendations, 14 (93%) are based on moderate or high-quality evidence.

Antimicrobials

The current recommendation categorises acutely unwell hospitalised patients based on their likelihood of sepsis (categorised into high (probable), intermediate (possible) and low) and whether shock is present or not. This generates the following clinically relevant categories of patients with sepsis and corresponding recommendations for the timing of antimicrobial therapy (Box 15.1).

Box 15.1

Antimicrobial recommendations

The SSC guidelines do not make any recommendation on the use of antiviral agents. The recommendations for empiric antifungal therapy, empiric Methicillin-resistant Staphylococcus aureus (MRSA) coverage in patients at high risk of MRSA infection and two antimicrobials with gram-negative coverage for patients at risk of multidrug resistance are weak recommendations, based on very low quality of evidence. In these situations, the advice would be to follow local hospital antimicrobial guidelines.

Resuscitation Fluids

For adults with sepsis or septic shock, the use of crystalloids as first-line fluid for resuscitation is a strong recommendation based on moderate-quality evidence. The choice between balanced crystalloids (such as Ringer's lactate or Plasmalyte) and 0.9% saline is a weak recommendation. Importantly, the SSC guidelines make a strong recommendation based on high-quality evidence against using starch-based colloids for the resuscitation of patients with sepsis or septic shock. The SSC guidelines do not make any recommendations on the use of restrictive versus liberal fluid strategies in the first 24 hours of resuscitation in patients with sepsis and septic shock who still have signs of hypoperfusion and volume depletion. Although the management of early sepsis-induced hypoperfusion is evolving towards fluid-sparing and less invasive strategies many questions remain on the best approach to resuscitation. [77]

Vasoactive Drugs

For adults with septic shock, norepinephrine is strongly recommended as the first-line agent over other vasopressors. The blood pressure target is mean arterial blood pressure (MAP) greater than or equal to 65 mm Hg. If central venous access is immediately unavailable, a weak recommendation is provided for starting vasopressors peripherally to restore mean arterial pressure rather than delaying initiation until central venous access is secured. Further, for adults with septic shock on low to moderate dose of norepinephrine with an inadequate MAP, the weak recommendations are to add vasopressin instead of escalating the dose of norepinephrine, followed by adrenaline. If there is cardiac dysfunction and evidence of persistent hypoperfusion despite adequate resuscitation after achieving MAP targets, the weak recommendations are to add in either adrenaline or dobutamine.

Adjuvant Therapies

Corticosteroids

The SSC guidelines provide a weak recommendation for using corticosteroids (intravenous hydrocortisone 200 mg/day) in patients with septic shock who have ongoing vasopressor requirement ≥ 0.25 mcg/kg/min for 4 hours or longer. This recommendation is supported by the observations that whilst corticosteroids increase the number of vasopressor-free days (and shock resolution), they increase the risk of neuromuscular weakness without a clear benefit on mortality.

There are additional considerations for the use of low-dose corticosteroids in patients with sepsis. Subsequent to the publication of SSC guidelines, a randomised clinical trial concluded mortality benefit in patients with community-acquired pneumonia with a low risk of death, [78] the unequivocal beneficial effect of low-dose corticosteroids in COVID-19, [79] and the differential treatment effect (including harm) of hydrocortisone in subphenotypes of sepsis. [80]

Other Therapies

The SSC guidelines also provide weak recommendations against the use of levosimendan, as levosimendan was not superior to dobutamine in adults with sepsis in terms of mortality. Whilst there are no SSC recommendations for selective beta-1 blockers (such as esmolol and landilol), [81], [82] these drugs should be limited to testing in clinical trials. Currently, there is no role for use of vitamin C in patients with sepsis and septic shock. [83] Currently, there is no role for routine use of immunomodulatory drugs, such as intravenous immunoglobulins (IVIG or IVIGAM), [84] recombinant interleukin-7, [58] checkpoint blockers [61], [62] and TREM-1 inhibitors [85] in patients with sepsis or septic shock.

Future directions

Heterogeneity and Sepsis Subphenotypes

The clinical definition of sepsis encompasses a diverse group of patients, each exhibiting significant biological variation. This heterogeneity poses an obstacle to the development of effective therapies. To overcome this challenge, recent efforts have increasingly focused on the identification of distinct subgroups within the sepsis population. [86] These subgroups, characterised by either shared clinical features (subphenotypes) or underlying biological mechanisms (endotypes), could potentially offer predictive insights regarding responses to specific interventions or prognostic information about expected outcomes. [87]

Numerous studies have used routinely available clinical data to define sepsis subphenotypes. The most parsimonious example is the use of longitudinal temperature measurements. In a study involving 31,466 patients who arrived at the emergency department (ED) with suspected infection, group-based trajectory analysis revealed four distinct subphenotypes: normothermic, hypothermic, hyperthermic – fast resolvers, and hyperthermic – slow resolvers. [88] The ‘hypothermic’ group had the lowest C-reactive protein levels, the greatest requirement for vasopressors and mortality three times that of the ‘hyperthermic – fast resolving’ group.

In contrast, the ‘hypothermic-slow resolving’ subphenotype exhibited the highest levels of inflammatory biomarkers and the greatest mortality (10.2%). Other researchers have conducted unsupervised clustering on datasets incorporating various clinical, physiological and biomarker variables. [86] Notably, Seymour and colleagues identified four subphenotypes (labelled α, β, γ and δ) by employing K-means clustering on a cohort of 20,189 patients who had been part of previous observational studies and randomised controlled trials in sepsis. [89] These subphenotypes were identifiable upon presentation to the ED but did not correlate with the pattern of organ dysfunction or illness severity. Of these, the δ subphenotype was most closely associated with abnormal host-response markers and had the highest in-hospital mortality.

Arguably, true endotypes of sepsis are yet to be described, however, investigators have derived subphenotypes based on host transcriptomic features. Within the Molecular Diagnosis and Risk Stratification of Sepsis (MARS) observational cohort, four distinct subphenotypes (MARS 1-4) were identified. [90] Of these, the MARS 1 subphenotype, defined by decreased expression of genes related to innate and adaptive immunity, had the highest mortality. The four MARS subphenotypes were largely indistinguishable based on clinical characteristics. Similarly, Davenport and colleagues explored blood leukocyte gene expression data to discern subphenotypes in patients with sepsis resulting from community-acquired pneumonia. [91] This investigation identified two subphenotypes, Sepsis Response Signatures (SRS) 1 and SRS 2. The SRS 1 subphenotype was defined by features of immune suppression, endotoxin tolerance, T-cell exhaustion, metabolic derangement and a lower survival rate. Conversely, belonging to the SRS 2 subphenotype, which is relatively immunocompetent, has been linked to an increased risk of mortality when treated with hydrocortisone. [80] A differential response to hydrocortisone has also been observed between immunocompetent and immunosuppressed transcriptomic subphenotypes derived in an independent cohort, however, these are imperfectly aligned with the SRS subphenotypes. [92] More recently, differential response to activated protein C has been reported, which reinforces the need for subtyping in sepsis. [93] However, the current difficulty in relating different subtypes of sepsis,[94] highlights the need for a minimum set of rules for such endeavours.[21]

Whilst these studies advance our understanding of the heterogeneity underlying sepsis, there are remaining challenges to clinical application. Subphenotyping strategies must be temporally stable and computable early in the course of illness. In future, this may be achieved with the use of point-of-care biomarkers, machine learning or both.[95] In parallel, mechanistic studies are required to understand biologic differences between subphenotypes and to develop therapeutically tractable sepsis endotypes or sepsis immune response states.[21]

Conclusions

Sepsis remains a global healthcare challenge despite significant advances in our understanding of pathobiology, including immunobiology. Much has been done to increase public awareness of sepsis including the creation of World Sepsis Day and the formation of national bodies (e.g., Sepsis Trust UK, Sepsis Australia) to promote public engagement and fundraising. The current management should be grounded to realistic medicine with a high index of suspicion in any acutely unwell patient, prompt initiation of antimicrobial therapy, source control, resuscitation and organ support as required. As of 2025, there is no role for immunomodulation as the standard of care in all patients with sepsis. Addressing the biological heterogeneity may pave the way for targeted immunomodulation in the future.

Multi-organ dysfunction syndrome

Matthew J. Maiden and Sarah C. Sasson

Multi-organ dysfunction syndrome (MODS) is a complex process whereby an acute disease or injury precipitates the deranged function of several organ systems. MODS is common among patients in the intensive care unit (ICU) and accounts for 40% to 50% of deaths.[1,2] Hence, critical care clinicians require a sound understanding of the pathophysiology and management priorities for MODS.

History

During World War II, severely injured soldiers without thoracic trauma were noted to develop respiratory failure days following their initial injury. The incidence appeared related to the severity and duration of hypotension and the term ‘shock lung’ was used to describe the subsequent respiratory failure. It was postulated that hypoperfusion initially impaired pulmonary function and that other factors, including blood product transfusion, micro-emboli, fat emboli, endotoxin and excessive use of oxygen additionally contributed.[3]

Following the advent of ICUs, similar patterns of ‘remote’ organ failures were reported in critically ill patients following trauma, surgical haemorrhage, abdominal sepsis, pneumonia and pancreatitis.[4,5] Although many pathophysiological mechanisms for this have been described, it is still not clear why only some patients develop MODS.

Definition

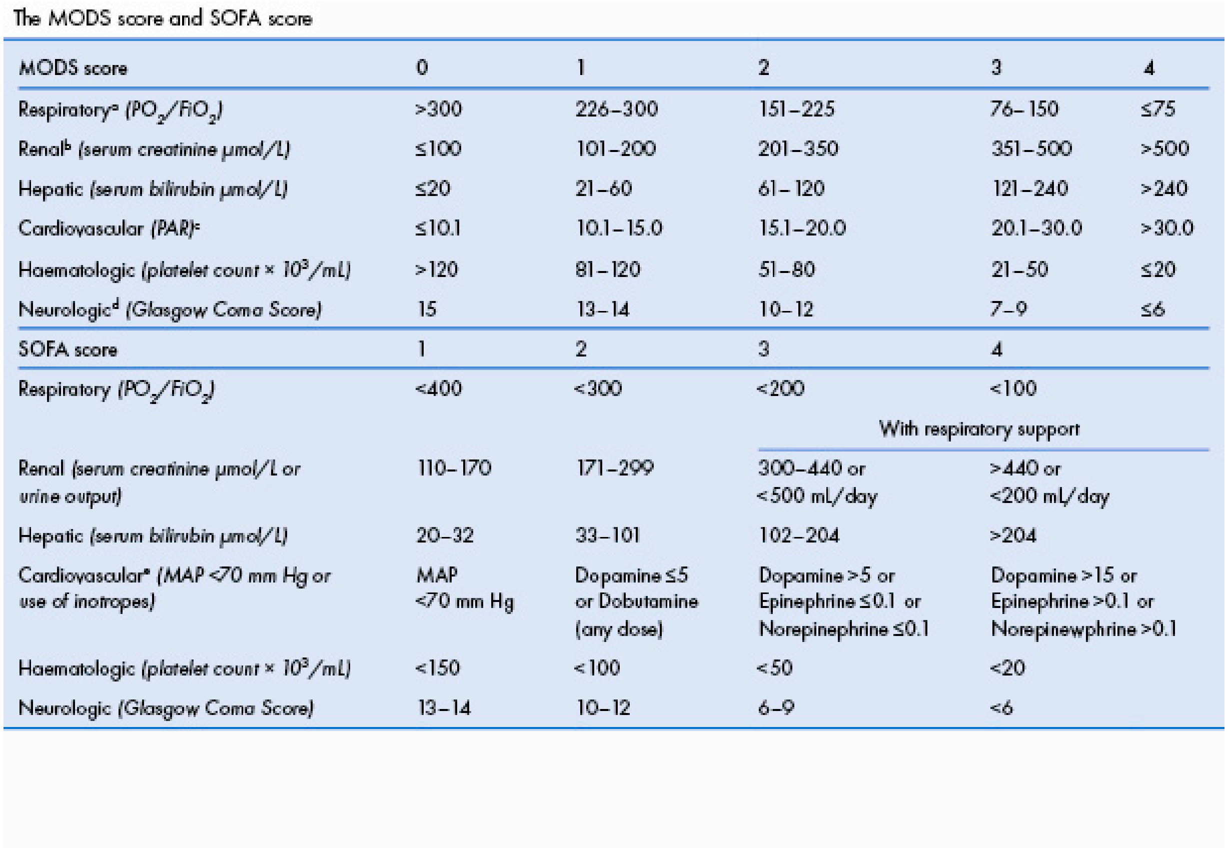
Over 40 different names have been ascribed to the phenomenon of ‘organ disease remote from the site of illness/injury’.[6] The terms ‘multiple system failure’ or ‘multiple organ failure’ have been commonly used.

A consensus conference in 1992 proposed the term ‘multiple organ dysfunction syndrome’ (MODS).[7] This term reflects a distinction between ‘dysfunction’ and ‘failure’. ‘Failure’ implies a dichotomous outcome that is often irreversible while ‘dysfunction’ describes a spectrum of organ impairment that may change over time. The term ‘syndrome’ was added to describe a pattern of multiple symptoms and signs that may have a similar pathogenesis.

However, this concept of MODS did not characterise or specify what constitutes an organ dysfunction. Subsequently, many classifications and scoring systems have been developed in an attempt to define and quantify the severity of MODS. These have varied according to which organ systems are assessed, which parameters are measured, and the thresholds for the organs to be considered dysfunctional.

The MODS and SOFA (sepsis-related organ failure assessment) scores were developed after the consensus definition of MODS (Table 16.1). They were primarily established to describe the severity of MODS and changes in major organ function over time.[8,9] For each of the six major organ systems, one aspect of dysfunction was chosen. Scores for each organ are equally weighted and summed to provide an overall score. The score at ICU admission and the change in score over the course of ICU stay correlate with mortality rate, with both the MODS and SOFA scores performing similarly.[10,11] These well-established scoring systems are widely used given their ease of application and association with mortality.

Table 16.1



The MODS score and SOFA score

MODS score	0	1	2	3	4
Respiratory[a] *(PO_2/FiO_2)*	>300	226–300	151–225	76–150	≤75
Renal[b] *(serum creatinine µmol/L)*	≤100	101–200	201–350	351–500	>500
Hepatic *(serum bilirubin µmol/L)*	≤20	21–60	61–120	121–240	>240
Cardiovascular *(PAR)*[c]	≤10.1	10.1–15.0	15.1–20.0	20.1–30.0	>30.0
Haematologic *(platelet count × 10^3/mL)*	>120	81–120	51–80	21–50	≤20
Neurologic[d] *(Glasgow Coma Score)*	15	13–14	10–12	7–9	≤6
SOFA score	1	2	3	4	
Respiratory *(PO_2/FiO_2)*	<400	<300	<200	<100	
			With respiratory support		
Renal *(serum creatinine µmol/L or urine output)*	110–170	171–299	300–440 or <500 mL/day	>440 or <200 mL/day	
Hepatic *(serum bilirubin µmol/L)*	20–32	33–101	102–204	>204	
Cardiovascular[e] *(MAP <70 mm Hg or use of inotropes)*	MAP <70 mm Hg	Dopamine ≤5 or Dobutamine (any dose)	Dopamine >5 or Epinephrine ≤0.1 or Norepinephrine ≤0.1	Dopamine >15 or Epinephrine >0.1 or Norepinewphrine >0.1	
Haematologic *(platelet count × 10^3/mL)*	<150	<100	<50	<20	
Neurologic *(Glasgow Coma Score)*	13–14	10–12	6–9	<6	

[a] P/F ratio is calculated without reference to the use or mode of mechanical ventilation, and without reference to the use or level of positive end-expiratory pressure.

[b] Serum creatinine measured without reference to the use of dialysis.

[c] Pressure-adjusted heart rate (PAR) is calculated as the product of heart rate (HR) multiplied by the ratio of the right atrial (central venous) pressure (RAP) to the mean arterial pressure (MAP): PAR = HR × RAP/MAP.

[d] The Glasgow Coma Score is preferably calculated by the patient’s nurse and is scored conservatively (for the patient receiving sedation or muscle relaxants, normal function is assumed, unless there is evidence of intrinsically altered mentation).

[e] Adrenergic agents administered for at least 1 h (doses given are in µg/kg/min).

However, there are limitations to these scoring systems. Firstly, these algorithms do not take abnormal baseline organ function into account. Patients with chronic disease may have elevated severity scores without being acutely unwell. Secondly, scores may incorporate the extent of treatment provided (or not provided). For example sedation, fluid resuscitation, oxygen administration and choice of vasoactive agents will all influence the scores. Thirdly, the scores are categorical rather than measured on a continuous scale. While this makes scores easy to calculate, they may not capture subtle changes in disease trajectory. Fourthly, the six organ systems in the scoring systems are considered using only one metric of their function. There are many other ways an organ may be considered dysfunctional besides those listed. Finally, there are many other dysfunctional organ systems that may contribute to MODS. For example gastrointestinal integrity and function are increasingly recognised as being important but are currently not included. Given these scoring systems were developed nearly 30 years ago, and with significant changes in practice, knowledge of disease and availability of data, there will be a need to reconsider how multi-organ dysfunction is defined and quantified. [12]

Aetiology of MODS

Almost any disease that invokes tissue injury can progress to MODS (Box 16.1). It occurs most commonly following a microbial infection. Of note, we propose the term 'sepsis-induced MODS' should now be replaced with 'infection-induced MODS', given that the current definition of sepsis is 'infection with accompanying organ dysfunction' (Sepsis-3). [13]

Box 16.1

Diseases that can progress to MODS

Infection (sepsis)

No infection (non-septic)

- Major trauma
- Burns
- Pancreatitis
- Aspiration syndromes
- Extra-corporeal circulation (e.g. cardiac bypass and ECMO)
- Large volume blood transfusion
- Ischemia-reperfusion injury

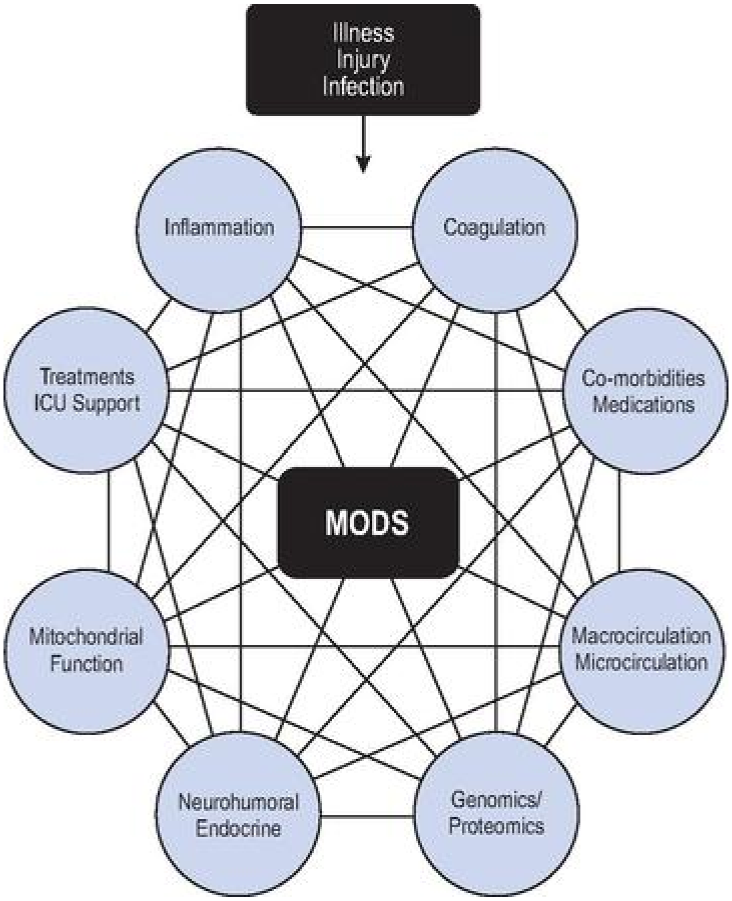
Autoimmune disease (e.g. vasculitis)
Haemophagocytic lymphohistiocytosis (HLH)
Thromboembolism
Major surgery
Heat-induced illness
Eclampsia
Poisons/toxins/medications

Diseases without microbial infection account for a smaller number of patients developing MODS but are an important consideration in the setting of acute illness and organ dysfunction. For example major trauma leads to MODS in about 30% of patients. [14] It occurs predominately in the first few days following injury and is most likely in patients with greater physiological derangement on presentation, and those administered more fluids and blood products. Even isolated traumatic brain injury can induce MODS, with cardiovascular and respiratory systems manifesting most of the non-neurological organ dysfunction. [15]

Diseases that can progress to MODS are discussed in other chapters of this text.

Pathogenesis

MODS is a systemic process with a complex pathophysiology. While systemic inflammation appears to be central to the development of MODS, a multitude of other factors also contribute. The pathogenesis of MODS is best conceptualised as a complex, dynamic, non-linear system involving a large number of variables that are highly interdependent [16] (Fig. 16.1).



Illness
Injury
Infection
Inflammation
Coagulation
Treatments ICU Support
Co-morbidities Medications
MODS
Mitochondrial Function
Macrocirculation Microcirculation
Neurohumoral Endocrine
Genomics/ Proteomics

The conceptual diagram presents a model in which a rectangular label reading illness, injury, infection points downward to a central rectangle labelled M O D S. Surrounding M O D S are eight circular nodes connected with bidirectional lines forming an interlinked network. The eight labels are inflammation, coagulation, co-morbidities medications, macrocirculation microcirculation, genomics proteomics, neurohumoral endocrine, mitochondrial function, and treatments I C U support. Each of these nodes is connected to M O D S and also interconnected with one another through multiple linking lines.

FIG. 16.1 Multi-organ dysfunction syndrome (MODS) results from a complex interaction of a number of different pathogenic processes. *ICU,* intensive care unit.

Inflammation

Inflammation is essential to contain infection and for tissue repair. However, the inflammatory response to injury, illness or infection may become dysregulated resulting in MODS and critical illness.[13, 17] Increased levels of pro-inflammatory mediators are associated with worsening organ dysfunction and MODS can be reproduced experimentally by infusion of inflammatory cytokines.[18, 19]

As a systemic inflammatory response appears to be central to the development of MODS, the term systemic inflammatory response syndrome (SIRS) was defined in conjunction with the definition of MODS.[7] However, SIRS is non-specific and provides little information about what is provoking the inflammation. It is important to recognise that clinical features of systemic inflammation may be an appropriate response to serious injury/infection and that most patients with these signs do not develop MODS.

Many inflammatory mediators have been identified and characterised over the last 50 years (Box 16.2). They are released from inflammatory cells, particularly pro-inflammatory (M1) macrophages, and interact with the immune, endocrine and nervous systems to mediate host defence and tissue repair. A study of adult patients with trauma found decreased expression of CD62L on neutrophils and decreased CD63 expression on both neutrophils and monocytes as possible biomarkers for the development of MODS.[20] With so many potential inflammatory mediators identified, further research is needed to determine which molecules are key pathological drivers in the development of MODS. Given the convoluted and amplified inflammatory responses that follow injury, there has been much interest in understanding the early cellular responses to injury and infection.

Box 16.2

Some of the inflammatory mediators associated with MODS

Interleukin-1β (IL-1β)
Interleukin-6 (IL-6)
Interleukin-8
Tissue necrosis factor-α (TNF-α)
Interferon-γ (IFN-γ)
Colony stimulating factors
Eicosanoids/platelet aggregating factor
Soluble adhesion molecules
Complement proteins
Nitric oxide
Heat shock proteins
Free radicals/reactive oxygen species
Pro-calcitonin
Angiopoietin
IL-1 receptor associated kinase (IRAK-1)

Nuclear Factor-κB (NF-κB) is a co-factor involved in the transcription of genes that encode inflammatory proteins, apoptotic signalling pathways and nitric oxide production. NF-κB is pre-formed in the cytoplasm and is activated when the inhibitory subunit (IκBα) is cleaved off, allowing NF-κB to translocate to the nucleus. NF-κB levels are increased in proportion to the severity of the disease. [21]

Toll-Like Receptors (e.g. TLR2, TLR4) are activated by bacterial products and necrotic cells. TLR activate NF-κB and other factors that transcribe inflammatory mediators. The process of TLR activation differs between microbial and non-microbial precipitants. [22] Pre-clinical studies targeting the non-microbial activation pathways have yielded less organ dysfunction while maintaining anti-microbial efficacy. Mutations of TLR4 are associated with an attenuated inflammatory response. [23]

High Mobility Group Box Protein 1 (HMGB-1) is an evolutionary conserved protein that potentiates the binding of inflammatory mediators to cells. It also acts as a nuclear co-factor that enhances the DNA transcription of many inflammatory mediators. Plasma levels of HMGB-1 increase in sepsis and trauma in proportion to the severity of the illness or injury.[24], [25] In experimental studies, anti-HMGB-1 attenuates the inflammatory response to infection, autoimmunity, ischaemia and trauma.[26]

Compensatory Anti-Inflammatory Response Syndrome (CARS)

There is increasing recognition that patients with sepsis display both immune hyper-inflammation and opposing immunosuppressive elements. This anti-inflammatory response has been termed the compensatory anti-inflammatory response syndrome (CARS)[27] and involves counter-regulatory mediators such as TGF- β and IL-10. Immunological features of CARS include apoptosis of lymphocytes leading to lymphopenia, release of IL-10 which suppresses TNF-α, decreased cytokine production and down-regulated HLA receptors on monocytes. Therapeutic targeting of CARS, for example using interferon-gamma (IFN-γ), granulocyte-macrophage colonystimulating factor (GM-CSF), interleukin(IL)-7 or checkpoint inhibitors such as anti-PD-1 are an area of current research.[28]

Just as an excessive pro-inflammatory response may contribute to MODS, an exaggerated anti-inflammatory response, which tends to occur later in the disease, can result in a state of immunosuppression and anergy.[29] Relative immunosuppression is often a feature of MODS and is thought to account for the late development of iatrogenic infections with organisms that are usually commensal or of low virulence (e.g. *Candida, Pseudomonas, Stenotrophomonas and Enterococcus*).

Coagulation

Tissue factors, endotoxin, bacterial antigens and cytokines can trigger the clotting system. Thrombin is produced at the site of infection or injury to isolate infectious sources and initiate tissue repair. However, products of the coagulation pathway are pro-inflammatory and the clotting system is central to the inflammatory response. For example activation of the thrombin receptor induces transcription of NF-κB and stimulation of pro-inflammatory sequelae.[30]

Coagulation is normally controlled by the endogenous anti-coagulant factors anti-thrombin III (AT-III; binds to thrombin and endothelium to release endothelial prostacyclin and inhibit platelet aggregation) and protein C (complexes with Protein S to inhibit Va and VIIIa). Levels of these anti-coagulants fall during critical illness proportional to the severity of MODS.[31], [32]

Endothelium

Vascular endothelium comprises a layer of endothelial cells and a layer of glycocalyx (Fig. 16.2). While endothelial cells comprise only a single layer of cells, they are distributed over the entire circulation and have a major influence on the integrity and function of the vascular network. The glycocalyx is a gel-like network of heparin molecules, glycoproteins and glycolipids that extend from the endothelial cell membrane into the vascular lumen. It also contributes to endothelial function including local inflammatory signalling, coagulation and detecting the shear forces of flowing blood.

The two-part diagram is labelled A and B. Part A is titled glycocalyx under physiological condition. It shows a structured endothelial surface with labelled components. An erythrocyte, plasma proteins, a platelet, a monocyte, and plasma proteoglycans are visible in the vascular space above the glycocalyx. The endothelial layer includes labelled molecules such as E C S O D, N O-synthase, V W F, T F P I, and antithrombin. Text labels beside this layer mark the glycocalyx, endothelium, and subendothelial space. Additional labels at the bottom describe functions such as shear induced N O-synthesis and superoxide dysmutation under endothelial function, a sieving barrier under permeability, inhibition of platelet adherence and coagulation regulatory factors under coagulation, and prevention of leukocyte adhesion under inflammation. Part B is titled perturbed glycocalyx. It depicts a disrupted endothelial surface. Labelled features include an erythrocyte, plasma proteins, plasma proteoglycans with upward arrows, and an increased presence of fragmented or distorted structures. Adhering platelets are shown on the endothelial layer. Molecular labels such as E C S O D, N O-synthase with a downward arrow, V W F with upward arrows, T F P I, and antithrombin are included. The endothelial surface is labelled as perturbed glycocalyx, endothelium, and subendothelial space. Additional annotations at the bottom describe reduced N O availability and increased oxidative stress, leakage of macromolecules, increased platelet adherence and thrombin generation, and increased leukocyte adhesion and diapedesis.

FIG. 16.2 Schematic representation of the glycocalyx. (A) Endothelial glycocalyx regulates nitric oxide synthase, superoxide dismutase, serves as a physical barrier for macromolecules and attenuates platelet and leukocyte adhesion. (B) Endothelial dysfunction leads to increased vascular permeability, activation of coagulation and cellular adhesion/migration. *AT* , Anti-thrombin; *EC-SOD* , extracellular superoxide dismutase; *ICAM* , intercellular cell

adhesion molecule; *NO* , nitric oxide; *TFPI* , tissue factor pathway inhibitor; *VCAM* , vascular cell adhesion molecule; *vWF* , von Willebrand factor. (From Nieuwdorp M, et al. The endothelial glycocalyx: a potential barrier between health and vascular disease. *Curr Opin Lipidol.* 2005;16(5):507-511.)

The endothelium provides a dynamic barrier between the circulation and interstitial tissue. Normally the endothelium is relatively impermeable to inflammatory cells, proteins and plasma. However following tissue injury, endothelial function and glycocalyx structure alter to permit inflammatory cells to reach the site of injury. As might be expected, the degree of disturbance to the endothelium and glycocalyx appears to be more pronounced in patients who develop MODS.[33,34] Parameters of endothelial structure and function remain an experimental tool and their clinical utility remains to be determined.

Neuro-Immune and Hormonal Responses

The autonomic nervous system interfaces with the immune system and contributes to the inflammatory response. Afferent fibres of the vagus nerve can be stimulated by immune mediators leading to efferent signalling to the spleen and other lymphoid organs. This results in acetylcholine release which activates cholinergic receptors on macrophages and a reduction in their release of pro-inflammatory cytokines.[35] In animal models, interruption of this pathway by vagotomy results in increased systemic inflammation,[36] but modulation of this mechanism in humans with sepsis has not been clearly demonstrated. Some immune mediators also act as neuro-hormones providing neural feedback regarding the inflammatory state (Fig. 16.3).[37,38]

The schematic presents a sequence beginning on the left with multiple pathogen types and molecular elements such as spherical particles, rod-shaped bacteria with flagella, and clustered dots. These elements move toward membrane-bound receptors on a curved bilayer membrane. The central part of the diagram features the label N F kappa B, positioned within the cell. A signalling pathway leads from N F kappa B to the right side, where a brain structure is shown. Lines extend from the N F kappa B label to the brain, with additional intermediate labels such as T N F, I L 1, I L 6, and H M G B 1, representing cytokines or signalling molecules. The visual depicts a conceptual flow from pathogen exposure to intracellular receptor activation and downstream brain involvement through labelled molecular signals.

FIG. 16.3 Neuro-humoral factors influence the response to illness/injury. *HMGB1,* High mobility group box protein 1; *IL,* interleukin; *NF-κB,* nuclear factor-κB; *TLR,* toll-like receptors; *TNF,* tissue necrosis factor. The ‘stress response’ to critical illness involves the release of adrenal hormones. This is controlled by the hypothalamic secretion of corticotropin-releasing hormone (CRH) under direct neural control and modulated by circulating cytokines. Inadequate hypothalamic-pituitary-adrenal response to critical illness or glucocorticoid resistance may contribute to MODS.

Changes to thyroid metabolism occur during MODS. In health, thyroxine (T4) is metabolised to the metabolically active tri-iodothyronine (T3), while during critical illness changes to the de-iodination pathways favour the production of the biologically inactive reverse-T3. The consequential fall of plasma T3 levels is proportional to the severity of MODS and is independently associated with mortality.[39, 40]

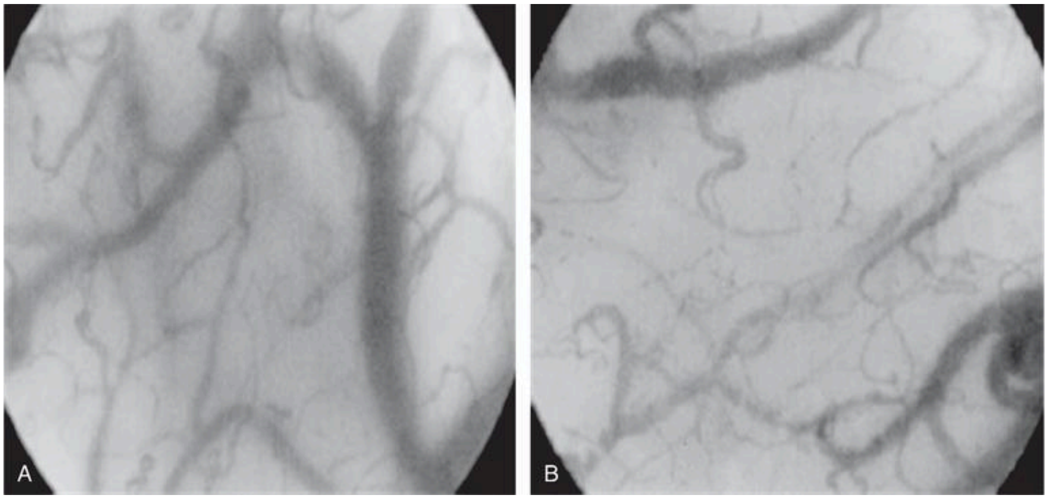
Macro-Circulatory Changes

Inadequate circulation of oxygenated blood can lead to impaired organ function. While circulatory shock can initiate and perpetuate MODS, and is usually fatal if not treated, not all patients with MODS have impaired cardiac output or oxygen delivery. In fact, many patients with MODS have preserved or increased oxygen delivery. Attempts to prevent MODS by further augmenting oxygen delivery such as by transfusing red cells or increasing cardiac output have not improved outcomes.[41]

Vascular tone is often reduced in MODS secondary to excessive nitric oxide (NO). Nitric oxide synthase (NOS) is found in endothelial cells and is induced by inflammatory mediators. Nitric oxide is toxic to micro-organisms, acts as an inflammatory signal, produces vascular smooth muscle relaxation and maintains patency of the micro-circulation. However excessive NO also leads to ‘vasoplegia’ with low systemic vascular resistance and arterial pressures, venodilation and altered blood flow to the organs.

Micro-Circulatory Changes

Reduced blood flow through the micro-circulation is associated with organ failure and death.[42] Microvascular thrombi, reduced red blood cell deformability and increased blood viscosity contribute to reduced microvascular flow and limited oxygen delivery to the cells.[43,44] Excessive NO alters the tone of the micro-circulation contributing to mismatched microvascular flow and shunting.[45,46] The formation of interstitial oedema through endothelial permeability further restricts diffusion between the micro-circulation and cells. Bedside visualisation of the micro-circulatory changes, for example through using hand-held microscopes to examine sublingual capillary beds, provides fascinating insights into the pathophysiology of MODS, but currently remains in the research domain (Fig. 16.4).[35]



The pair of circular angiographic sections is labelled A and B. Part A shows a dense vascular network with multiple branching vessels of varying calibres distributed across the field. The vessels exhibit a combination of straight and curved trajectories, with several prominent central vessels surrounded by finer peripheral branches. Part B presents a different distribution of blood vessels, with relatively fewer large vessels and an increased presence of tortuous and coiled branches throughout the field. The vessels in Part B exhibit diverse orientations and complex interconnections. Both views provide structural visualisation of vascular architecture through contrast-based imaging, focusing solely on vessel morphology.

FIG. 16.4 Sublingual micro-circulatory changes seen in sepsis-induced multi-organ dysfunction syndrome. (A) Healthy volunteer and (B) a patient with septic shock. Note the rich density of large and small vessels in the healthy volunteer and the decrease in density of small vessels in sepsis. (Reprinted with permission of the American Thoracic Society. Respir Crit Care Med . 2002;166:98–104. Official Journal of the American Thoracic Society.)

Cell Death Pathways

Several cellular death pathways can be upregulated during sepsis, including apoptosis, necrosis, necroptosis, NETosis, pyroptosis and autophagy-induced death. Apoptosis is controlled cellular death that does not provoke inflammation. It is an essential process for normal coordinated control of populations of cells and is involved in cell ageing, immune regulation, epithelial cell turnover and resolution of inflammation. During critical illness, apoptosis is increased in lymphocytes and in cells that typically have a barrier function (e.g. gut epithelium and vascular endothelium). [47] This increases susceptibility to further insults. In contrast, apoptosis of neutrophils is delayed and may lead to an exaggerated inflammatory response. Caspases are enzymes central to the regulation of apoptosis and may provide a therapeutic target.

Necrosis is a non-programmed, energy-independent cell death that can be triggered by pathogenic virulence factors and tissue hypoxia. Necrosis can also promote local inflammation through the release of alarmins such as HMGB1. [48] However, MODS appears to be primarily a functional rather than structural disorder. Cell necrosis is an uncommon finding in post-mortem examination of organs that have failed due to MODS, [49] and a prospective experimental study of renal tissue in an experimental model of MODS revealed renal dysfunction occurred without any features of cellular necrosis. [50]

Necroptosis is a recently identified mechanism of programmed cell necrosis that is mediated by receptor-integrating protein kinase-1 (RIPK1). [51] , [52] It can be triggered by a range of inflammatory mediators and is thought to primarily control intra-cellular microbial infection. Necroptosis is also seen in many other disease processes, and its role in MODS is an area of ongoing research.

Mitochondrial Dysfunction

Mitochondrial function alters in MODS, and cells appear to enter a state of 'hibernation' where metabolic activity is reduced and oxygen utilisation is limited.[53], [54] This may be induced by circulating factors such as thyroid hormone, glucocorticoids, catecholamines and cytokines.[55] Interestingly, patients who develop MODS, have a distinct profile of beta-oxidation, gluconeogenesis and citric acid cycle proteins.[56] This implies that there may be a metabolic predisposition to developing MODS. Mitochondrial dysfunction also occurs within immune cells and may contribute to an altered immunological response, production of reactive oxygen species (ROS) and release of mitochondrial DNA which acts as a damage-associated molecular pattern (DAMP) molecule.[57] Recovery of mitochondrial function in critical illness is associated with enhanced survival, and there is interest in the therapeutic potential of mitochondria-targeted therapy (e.g. carnitine).[58-60]

Comorbidities

An important consideration in the development of MODS is the patient's pre-morbid organ function. Patients with pre-existing organ disease are more likely to have further deterioration of organ function following an acute illness (e.g. compromised respiratory reserve in fibrotic lung disease, limited renal function in diabetic nephropathy, reduced marrow response in chronic leukaemia and impaired hepatic function in alcoholic liver disease). These patients have a lower threshold for developing MODS.

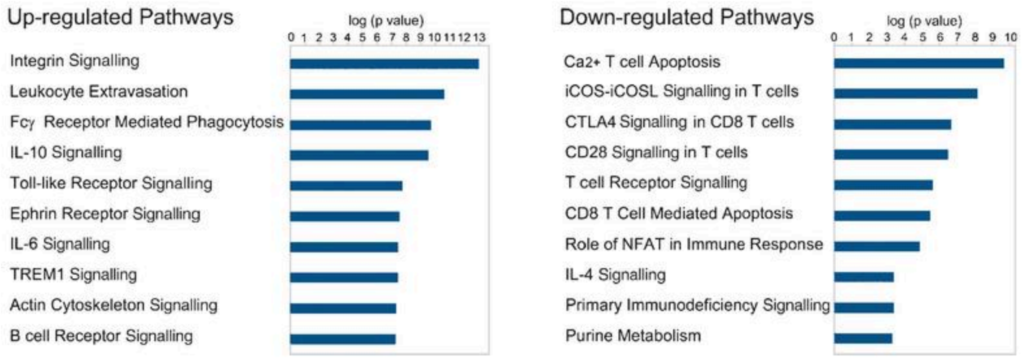
Iatrogenesis

The recognition of MODS corresponded with the development of intensive care support. It may be that some ICU interventions increase the risk of developing MODS or propagate the process once it is initiated. For example the incidence of acute respiratory distress syndrome (ARDS) and its mortality has reduced substantially since the recognition of that larger tidal volumes and overzealous parenteral fluid administration were contributing to lung injury.[61], [62] Other ICU interventions such as parenteral fluids (type and volume), immobility, artificial cooling, extra-corporeal circulatory support, catecholamines, medications, nutrition supplements and blood products may contribute. Providing evidence-based supportive care is a vital aspect of preventing MODS.

Genetics

It has been proposed that genetic factors contribute to the heterogeneity of MODS. Variants in the genes coding for TNF-α, TLRs, NF-κB, interleukin-1 receptor kinase and caspase-12 have been related to the severity of organ dysfunction and extent of ICU supports following sepsis.[63,64] Similarly, in patients undergoing elective abdominal aortic aneurysm repair, analysis of pre-operative leucocyte genes predicted which patients subsequently developed MODS.[65]

A landmark study longitudinally examined the leucocyte transcriptome from patients with severe trauma, severe burns, healthy volunteers exposed to endotoxin and matched healthy controls.[66] Over 80% of the leucocyte transcriptome was altered, with RNA expression patterns typically representing stimulation of innate immunity and suppression of adaptive immunity (Fig. 16.5). The number of genes with decreased expression was greater than the number of genes where expression was increased, and half of the altered gene expression had not returned to baseline by 28 days. The transcriptomic changes were remarkably similar between major trauma, extensive burns and endotoxin exposure.



The pair of bar charts is titled Up-regulated Pathways and Down-regulated Pathways. The left chart, titled Up-regulated Pathways, features ten horizontal bars representing biological signalling pathways. These pathways include integrin signalling, leukocyte extravasation, F C gamma receptor mediated phagocytosis, I L-10 signalling, toll-like receptor signalling, ephrin receptor signalling, I L-6 signalling, T R E M 1 signalling, actin cytoskeleton signalling, and B cell Receptor Signalling. The horizontal axis is labelled log p value and ranges from 0 to 13, with most bars extending beyond value 6. The right chart, titled Down-regulated Pathways, presents ten bars with corresponding horizontal axis values ranging from 0 to 10. The listed pathways include C a 2 plus T cell Apoptosis, I C O S I C O S L signalling in T cells, C T L A 4 signalling in C D 8 T cells, C D 2 8 signalling in T cells, T cell receptor signalling, C D 8 T cell mediated apoptosis, role of N F A T in immune response, I L 4 signalling, primary immunodeficiency signalling, and purine metabolism. Each pathway is represented by a bar of varying length corresponding to its log p value.

The Gut in MODS

There is evidence that the gut and its enteric micro-organisms provide an inflammatory focus during critical illness. Normally, organisms in the gut remain commensal due to bowel wall integrity and maintenance of the normal micro-flora ecosystem. However, when normal conditions are disturbed (e.g. bowel mucosal changes, altered gastric pH, anti-microbial use, overwhelmed reticulo-endothelial macrophages), the enteric organisms can invade and perpetuate an inflammatory response. Similarly, gut digestive enzymes can enter the circulation through compromised gut epithelium, contributing to the pathophysiology of MODS. [67] For this reason, the gut has been described as the 'motor' of MODS. [68] Early studies of gut decontamination in critical illness illustrated a survival benefit, and a recent large trial of oral, enteral and parenteral antibiotics to decontaminate the digestive tract found a non-significant trend towards reduction in mortality. [69] Balancing the risk of inducing anti-microbial resistance may temper the implementation of this practice.

Clinical Features of MODS

There is not a typical constellation or time course of organ dysfunction that describes MODS. Some patients may develop only mild organ dysfunction that, with supportive treatment, resolves in days, while others can develop fulminant MODS progressing rapidly to death.

Which organs become dysfunctional and the timing of their dysfunction depends on the patient's age, the inciting injury or illness, pre-morbid organ function, extent and duration of physiological derangement, the treatments provided and consideration of all the pathogenesis factors discussed earlier.

Identification of MODS as a discrete pathological entity has been difficult due to a lack of agreement about what characterises organ dysfunction. There are a variety of ways for measuring organ dysfunction;

clinical features, monitored physiological derangement and altered biochemical markers. Each organ system can manifest dysfunction in a multitude of ways. For example the respiratory system can be considered dysfunctional based on hypoxia (e.g. $PaO_2:FiO_2$ ratio), hypercarbia, reduced compliance, radiological change, extent of ventilatory supports or lavage fluid content. The processes that lead to changes in these parameters can be divergent and therefore defining an organ dysfunction based on a single variable is inadequate to encompass the full spectrum of disease.

Given the heterogeneity of acute organ dysfunction and emerging insights into underlying mechanisms, there may be a move away from considering MODS as a syndrome but rather a collection of specific diseases. These may be characterised based on a range of observable clinical features (phenotype) rather than just one parameter, and further informed by more specific pathobiological mechanisms (endotype), such as genotypes, inflammatory profiles, metabolic pathways and evolving biomarkers. As the availability of data and new information expands, informatics will play a key role in maximising the use of new knowledge to better understand the different patterns of multi-organ dysfunction. [12]

Therapies for MODS

MODS treatment priorities are:

1. Early recognition of illness.
2. Early resuscitation.
3. Early definitive treatment.
4. Organ support.
5. Consideration of pre-morbid disease.
6. Prevention of secondary injury/insults.

The focus of management in MODS should be treatment of the inflammatory focus (e.g. remove source of sepsis, repair injured tissue, control blood loss, debride burns, stabilise long bone fractures). Aspects relating to early recognition of the deteriorating patient, resuscitation, specific disease treatments and the methods of organ support are covered in other chapters.

Specific therapies that target the pathogenesis of MODS continue to be extensively studied. Each of the aforementioned pathophysiological processes has been targeted in pre-clinical and clinical trials. Despite promise in pre-clinical studies, no therapy has proven clinical efficacy in the treatment of MODS. The fact there is no ‘magic bullet’ for the treatment of MODS is not surprising given the complexity and variability of the pathophysiology, the lack of standardised treatments for some diseases, and uncertainty regarding optimal timing of adjunctive therapy. This further supports the need to develop contemporary insights into MODS and therapeutics that are specific to different phenotypes and endotypes of organ dysfunction.

Inflammation Modulating Therapies

Pro-inflammatory mediators have been a logical therapeutic target in MODS. In pre-clinical studies many of these agents have provided physiological benefit, reduced severity of organ dysfunction and improved mortality. However, none have proven efficacy in clinical trials and some have worsened outcomes. [70] For example pre-clinical studies of anti-TNF-α antibodies and soluble TNF receptors in bacteraemic primates, suggested that neutralising TNF-α improved organ function and reduced mortality. [71] However, not only did clinical trials fail to show a benefit, but higher doses increased mortality. [72] Similarly, the following agents have shown encouraging results in pre-clinical trials but no efficacy or adverse outcomes in subsequent clinical studies: endotoxin antibodies, non-steroidal anti-inflammatory drugs, IL-1 receptor antagonists, PAF antagonists, bradykinin antagonists, IFNγ, NOS inhibition, NO antagonists, AT-III concentrate and activated protein C and vitamin C.

The lack of clinical efficacy of immuno-modulating therapies for MODS may reflect misplaced attention on the harmful effects of cytokines rather than considering their beneficial role. While inflammatory mediators are associated with MODS, they are also vital for the control of infection, tissue repair and healing. Furthermore, the pro-inflammatory mediators have downstream effects that ultimately attenuate inflammation. While elevated concentrations of pro-inflammatory cytokines are clearly associated with MODS, reduced levels are also associated with increased mortality. [19, 73] Given the process of inflammation involves a complex interplay of pro- and anti-inflammatory mediators it may be that targeting one pro-inflammatory mediator is inadequate for the severity of inflammation in MODS.

Future therapies to assist with recovery from MODS may aim to control excess inflammation without interfering with the essential components of the inflammatory process. Agents that modulate the inflammatory process without diminishing anti-microbial mechanisms are currently being investigated.

Hormones

Glucocorticoids have been heavily investigated in the setting of MODS. High-dose steroid treatment is known to broadly suppress the inflammatory response but when trialled in critically ill patients with infection-induced MODS proved to be harmful. [74] As MODS may be associated with relative adrenal insufficiency and/or glucocorticoid resistance, lower-dose steroid treatment has been investigated. Initial studies suggested that patients with septic shock and limited response to administered corticotropin had mortality benefits from steroid replacement. [75, 76] However, in the CORTICUS trial, which studied a broader group of septic patients, hydrocortisone did not provide a mortality benefit. [76] Most recently, the ADRENAL study of 3800 ventilated patients with septic shock found that hydrocortisone (200 mg/day) slightly reduced the duration of catecholamine infusion but did not alter mortality. [77]

Thyroid hormone has received relatively little attention despite markedly reduced T3 concentrations during critical illness and the physiological plausibility that this may contribute to cell hibernation in MODS. Clinical trials in cardio-thoracic ICU patients with low T3 suggested replacement improves cardiovascular function, [78] however, in controlled experimental septic shock studies, providing supplementary T3 appeared physiologically inert. [79] Whether the cells are regulating their own T3 exposure by altering hormonal uptake or clearance is being investigated.

Blood Purification

Purification of blood through plasma exchange can remove both pro- and anti-inflammatory mediators from the circulation. There have been some investigations into the use of plasma exchange in sepsis, with one small single-arm study reporting a reduction in IL-1β and IL-6 and a reduction in noradrenaline requirements following intervention. [80] These findings are preliminary and require validation in larger randomised clinical trials. [81] The use of extra-corporeal membranes to filter and/or adsorb inflammatory mediators has been conceptually appealing but has not improved patient outcomes. [82], [83]

Nutrition

MODS is a hyper-catabolic state and nutritional support is required to ensure adequate energy, protein, fatty acids and trace elements. However, the ideal energy, protein and macronutrient composition in MODS is uncertain. A large clinical trial of enteral nutrition provided to critical patients found no benefit of providing more energy-dense feed. [84] A similar study is now being conducted to determine the effect of providing enteral nutrition with higher protein content. Supplementing enteral nutrition with amino acids (e.g. arginine and glutamine), nucleotides, fatty acids (e.g. omega-3 and γ-linoleic acid) and antioxidants (e.g. selenium) have been popular investigation targets, but have not improved patient outcomes.

Outcomes

Outcomes from MODS appear to have improved over time. In Australia and New Zealand, mortality of septic and non-septic patients in ICU decreased by 40% to 50% during the period 2000–2012, even after adjustment for important covariates such as severity of disease, comorbidities, type of hospital and admission diagnosis. [85] As no specific therapies have been developed that directly ameliorate MODS, the improved outcomes are likely to reflect a greater awareness of the diseases that can progress to

MODS, the importance of timely resuscitation, prompt treatment of the inciting disease and the application of evidence-based supportive care.

It is important to remain cognisant that many of the pathophysiological processes leading to MODS are part of a complex interdependent system that *usually* leads to the resolution of an acute illness/injury. Caution needs to be applied when considering the physiological changes that occur during a critical illness and whether treating these changes is beneficial for each individual patient. Conversely, we must remain aware that some patients develop an exaggerated response to an acute illness/injury, progressing to MODS, permanent organ injury or death. How to identify which patients will progress to MODS and how they are best managed is a research priority.

Genetics in sepsis

Jeremy Cohen, David Evans and Bala Venkatesh

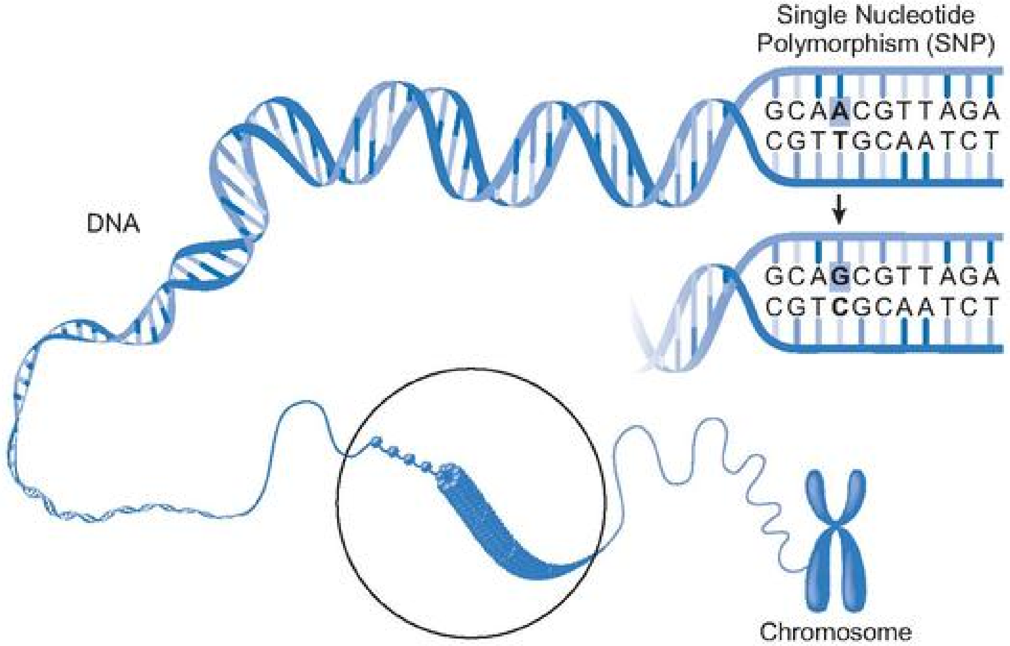
Introduction

Improvements in our understanding of the pathobiology of sepsis have led to a recent re-evaluation of how the disease is defined, leading to the current consensus definition of sepsis as ‘life threatening organ dysfunction caused by a dysregulated host response to infection’. [1] It is clear that there is substantial heterogeneity in the host response, the magnitude of which is influenced by a number of factors: patient co-morbidities, pathogen virulence, site of infection and host genetics. In the last decade, there has been substantial research into investigating the contribution that genetic variation makes to this heterogeneity and an understanding of this is an essential part of developing future management strategies. In this review, developments in genomics which have led to a greater appreciation of the importance of genetic factors in the outcome of sepsis are described, along with how this might influence future research and treatment.

Basic definitions

Deoxyribonucleic acid (DNA) is the chemical compound inside the nucleus of a cell that carries the genetic instructions to make proteins and contains the hereditary information that is transmitted from parents to offspring. Each DNA molecule consists of two paired strands of repeating units called nucleotides, wrapped around each other in a double helix structure (Fig. 17.1). Each nucleotide comprises a sugar molecule (deoxyribose), a phosphate group and one of four nitrogenous bases – adenine (A), thymine

(T), guanine (G) or cytosine (C). The bases of nucleotides from one strand pair with complementary bases from nucleotides on the other strand so that an ‘A’ nucleotide always pairs with a ‘T’ nucleotide, and a ‘C’ nucleotide always pairs with a ‘G’ nucleotide. The sequence of bases along the length of the DNA molecule encodes the genetic information contained within each cell and is virtually identical in all cells in an individual (gametes and some immune cells being an exception to this rule).



Single Nucleotide Polymorphism (SNP)
GCAACGTTAGA

DNA
Chromosome

The schematic presents a structural flow from D N A to a chromosome. On the left, a coiled D N A double helix transitions into a condensed chromosomal form at the lower right corner. A circular magnified section in the centre shows part of the D N A winding around histone-like structures, connecting the double helix to the chromosome. On the upper right, a zoomed view labelled single nucleotide polymorphism shows a double-stranded sequence with the top strand reading G C A A C G T T A G A and the bottom strand reading C G T T G C A A T C T. Below this, the altered version presents the top strand as G C A G C G T T A G A and the bottom strand as C G T G C G A A T C T. The change is marked by a single base substitution where an adenine is replaced by a guanine in the upper strand and a thymine is replaced by a cytosine in the lower strand. This illustrates a point mutation occurring within the D N A sequence as it relates to chromosomal structure.

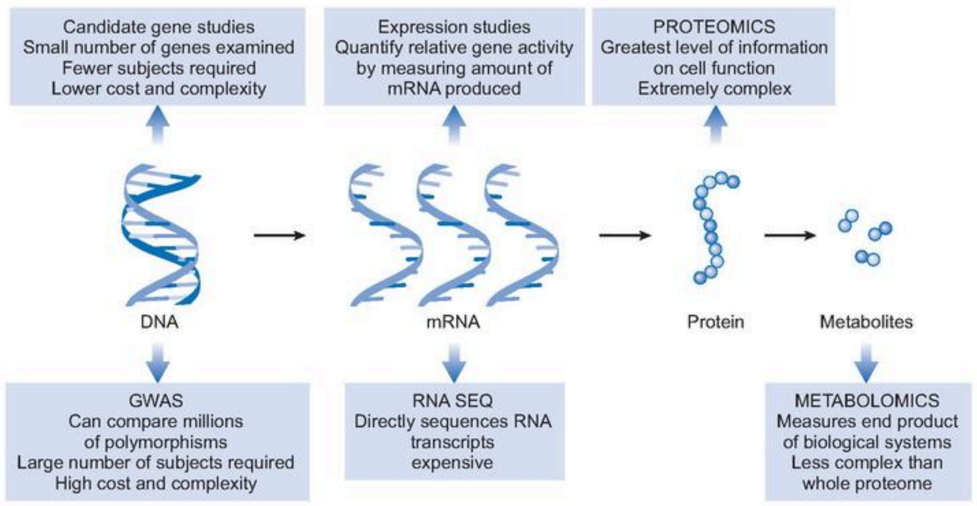
FIG. 17.1 Single nucleotide polymorphism (SNP). *DNA* , Deoxyribonucleic acid.

The DNA in the nucleus of cells is arranged into discrete linear structures called chromosomes. In each nucleus, there are 23 pairs of chromosomes, with one chromosome from each pair being inherited from each parent. The total amount of hereditary information encoded in the DNA sequence across all 23 pairs of chromosomes is known as an individual's genome and consists of over 3 billion nucleotide pairs.

Within the genome are elements called genes, discrete segments of DNA that code for proteins. There are estimated to be around 25,000 genes in the human genome. Genes serve as templates for making messenger RNA (mRNA) molecules through a process known as transcription. The mRNA transcripts travel out of the nucleus into the cytoplasm where they are subsequently used to make the polypeptides that form proteins, through a process known as translation. Genes comprise introns and exons; exons are regions that are transcribed into mRNA and may or may not code for proteins. Introns are initially transcribed but are removed from the mature mRNA by a process called splicing. Introns may many contain sequences that regulate gene expression.

While the vast majority of the genome (99.9%) of any two unrelated individuals is identical in terms of the DNA sequence, sequence variation can occur in a number of ways. The most commonly studied form of variation is called a single nucleotide polymorphism (SNP – see Fig. 17.1). A SNP is a DNA sequence variation that occurs when a nucleotide (A, C, T or G) is substituted for one of the others at a single position in the genome. For example, where there is typically an 'A' nucleotide at a particular location in the genome in the general population, some individuals might be found to have a 'G' nucleotide. There are over 10 million known common SNPs across the human genome. Whilst the majority of these changes produce no observable effects, some of them have measurable effects on humans including causing, or at the very least, altering the risk of disease. For example, some SNPs in genes may produce changes in the amino-acid sequence of their corresponding proteins and therefore exert a detrimental effect on protein function. Other SNPs might produce changes in the rate at which a particular gene is transcribed. Within the context of sepsis, investigators are interested in seeing whether genetic changes like these may explain some of the considerable inter-individual variation in the risk of sepsis and/or the prognosis of individuals unfortunate enough to suffer from the condition.

This chapter will examine the evidence that there is a genetic basis for the susceptibility to (and the response to) sepsis. It will then describe two broad strategies that have been used to try and understand the genetic basis of sepsis: genetic association studies (including candidate gene, genome-wide association studies, whole genome sequencing studies and Mendelian randomisation studies) which attempt to find a correlation between genetic variation and risk of/response to sepsis, and studies that examine differences in the expression of genes across the genome (including microarray-based and RNA-seq-based studies) (Fig. 17.2).



Candidate gene studies
Small number of genes examined
Fewer subjects required
Lower cost and complexity
Expression studies
Quantify relative gene activity
by measuring amount of
mRNA produced
PROTEOMICS
Greatest level of information
on cell function

Less complex than
whole proteome

The diagram presents a left-to-right sequence from D N A to metabolites. The first element is a D N A double helix leading to three strands of M R N A, followed by a protein structure composed of connected circles, and finally to smaller circular metabolites. Above the D N A is a label explaining candidate gene studies, which involve a small number of genes, fewer subjects, and lower cost and complexity. Below the D N A is a label for G W A S, which can compare millions of polymorphisms, requires a large number of subjects, and involves high cost and complexity. Above the M R N A is a label for expression studies, describing the quantification of gene activity by measuring M R N A levels. Below the M R N A is a label for R N A S E Q, which directly sequences R N A transcripts and is noted to be expensive. Above the protein is a label for proteomics, described as providing the greatest level of information on cell function and being extremely complex. Below the metabolites is a label for metabolomics, described as measuring the end product of biological systems and being less complex than the whole proteome. Arrows connect each stage, illustrating the molecular progression from D N A transcription through translation to metabolic end products.

A glossary of terms can be found at the end of the chapter.

Family Studies

Genetic influences on lifespan have been recognised for many years. [2] In 1988 Sorenson and colleagues examined Danish adoption records and demonstrated that in adopted children whose biological parent had died before the age of 50 from an infective cause, the relative risk of death from infection was increased fivefold. There was no corresponding increase in risk to the child if it was the adoptive parent who died from the same cause. [3] This elegant study implied that genetic factors were an important determinant of outcome from infection and so served as the foundation for future work in this field. Further analyses of this cohort suggested that genetic factors had a stronger influence on the risk of dying from an infection compared to the risk of acquiring one, suggesting that acquisition and prognosis are likely to involve different sets of genetic and environmental risk factors. [4] Twin studies have also provided valuable information. Comparing outcomes in monozygotic twins who are genetically identical to those in dizygotic pairs who on average share only half their genetic material can give an estimate of the relative contribution from hereditary factors. An increased concordance in susceptibility between monozygotic relative to dizygotic twins using this technique has been demonstrated in tuberculosis, sinusitis and *Helicobacter pylori* infections. [5-7]

Candidate Gene Studies

Molecular genetic investigations into sepsis have been based on two approaches. Historically the first, more widely used and simpler approach was the candidate gene study. This technique relies on first identifying a gene or genes that are likely to be implicated in the pathobiology of the condition and subsequently comparing the allelic frequency of polymorphisms in those genes between cases and controls. The advantages of this sort of design are lower cost, fewer subjects are required to achieve a given level of statistical power, and the analysis is less computationally intensive. As the approach is hypothesis driven, any associations are likely to be biologically plausible. Given these advantages and the fact that the technology to perform genome-wide studies (see below) only became available over a decade ago, it is unsurprising that the majority of initial studies into the genetics of sepsis have utilised the candidate gene approach. A 2006 systematic review identified 147 association studies examining 51 separate polymorphisms. [8] Many of these initial studies have reported positive associations. For example, there are reports of examples of increased mortality in sepsis associated with polymorphisms in the C-Reactive protein gene, [9] the protein C gene [10] and genes for Toll-like receptors. [11] However, the candidate gene approach has many limitations, of which perhaps the most important is the low probability of correctly identifying genes of interest a priori. In a complex syndrome such as sepsis, there are likely to be many genes influencing the condition, some of which may be readily apparent from basic physiology, but others less so. Given that there are around 10 million common SNPs in the genome, the probability of correctly choosing one involved in the risk of sepsis a priori is likely to be vanishingly small. Furthermore, the 2006 review identified numerous problems associated with sepsis studies in particular. Sample sizes were low, with the investigators estimating that only 7% of the studies were adequately powered to detect realistically sized associations at the 80% level. More tellingly, there was poor replication between studies and given the undoubted heterogeneity in the condition, the effect sizes associated with genetic variants are likely to be very small.

Genome-wide association studies

Another approach is that of the genome-wide association study (GWAS). A GWAS typically utilises high throughput microarray technologies to compare the allelic frequency of hundreds of thousands of SNPs between cases and controls. In addition, a statistical technique called imputation [12] can be used to infer genotypes at markers across the genome that have not been physically typed on the genotyping chips, meaning that literally millions of SNPs and other genetic variants can be tested for association in a GWAS. Thus in contrast to candidate gene studies, a GWAS makes no a priori hypotheses as to likely genetic mechanisms of variability, as by their nature they examine a much larger area of the genome and have the potential to identify unanticipated associations, which could lead to novel therapeutic targets and better understanding of underlying biology. Another advantage of GWAS is that it permits statistical methods that allow investigators to detect and correct for potential underlying biases in genetic studies like population stratification, whereas this can be difficult to do in candidate gene studies. [13] These features suggest that GWAS may be a superior technique to candidate gene studies in examining a complex multifactorial condition like sepsis. However, to have sufficient statistical power to detect alleles with even moderate effect sizes (e.g. allelic odds ratios of >1.3) a sample population of well over 2000 cases and controls is required. [14] This requirement is especially problematic in sepsis. Performing large-scale trials in an intensive care environment is logistically complex and expensive, and often requires multicentre, international collaborations. There are very few published critical care trials of any intervention that approach the numbers required for an adequately powered GWAS. Thus despite the advantages that GWAS may offer there have been relatively few performed in sepsis.

Rautanen et al performed a GWAS on over 2000 patients from three cohorts admitted to intensive care units with sepsis of pulmonary origin, including patients from two randomised multicentre clinical trials. [15] They observed that a common variant in the FER gene appeared to have a significant protective effect; patients homozygous for the allele had 10% mortality at 28 days, compared to 15% for heterozygotes and 25% for the wild-type homozygous population, although the observed p value of 9.7×10^{-8} is above the commonly accepted value of $\alpha = 5 \times 10^{-8}$ for significance in a GWAS. The mechanism for the observed survival advantage is not yet clear; the FER gene codes for a non-transmembrane tyrosine kinase that may have a role in neutrophil chemotaxis. It is noteworthy that an attempt to replicate the findings of Rautanen et al. in a cohort of 740 patients with severe sepsis was unsuccessful.[16] However, this may reflect the relatively low sample size of the replication cohort and its mixed population. D'Urso et al. reported their results of a GWAS on the 493 patients with septic shock who were enrolled into the ADRENAL trial and 2442 population controls, using polygenic risk score analysis to assess genetic overlap between septic shock risk/mortality with clinically relevant traits. They were unable to replicate variants previously reported to be associated ($p < 1 \times 10^{-6}$ in previous scans) with susceptibility to and mortality from sepsis.[17]

A larger, more recent study, examining 2750 adult sepsis patients from the GEN-SEP and MESSI studies, identified three novel variants associated with lower 28-day survival but did not replicate any of the findings from previous publications.[18]

Given the difficulties associated with recruiting large numbers of patients into individual genetic studies, perhaps the most logical way forward will be to statistically combine the results of different sepsis GWAS in a meta-analysis.[19] This strategy has been spectacularly successful in elucidating the genetic aetiology of other complex traits and diseases,[20] although it remains to be seen how effective this will be in sepsis, given the likely underlying heterogeneity of the condition. It will also be important to differentiate between GWAS that examine the risk of sepsis versus studies that investigate the response to sepsis, as these may involve substantially different genetic aetiologies. A recent example of this technique demonstrated 49 genome-wide significant associations from data from over 24,000 patients with COVID-19.[21] A substantial proportion of this data was obtained from the GENOMICC study (https://genomicc.org). GENOMICC is an international research collaboration aimed at collecting a sufficiently large database of DNA samples from critically ill patients and healthy volunteers to allow more detailed research in this area. The study continues to actively support collaboration from across the globe.

As genetic technology has advanced, next-generation sequencing technology is enabling researchers to comprehensively examine the role of all genetic variation in the genome, in particular, the role of rare and low-frequency variants.[22] However, whole genome sequencing studies are currently in their infancy, and the very low statistical power to detect rare variants means that sequencing studies will need to be extremely large to detect low-frequency variants. Therefore until the cost of sequencing a genome approaches that of a microarray chip, it is likely that GWAS will remain the method of choice for the genetic analysis of complex traits and diseases like sepsis.

Mendelian Randomisation

Mendelian randomisation is an epidemiological method that can be used to investigate potential causal relationships between biomarkers and clinical outcomes using genetic data.[23] This makes the method potentially attractive for studying sepsis, where the cost of performing randomised controlled trials is prohibitive and time consuming. Mendel's Laws of Segregation and Independent Assortment dictate that genetic variants are transmitted randomly from parents to their offspring. Consequently, the combination of alleles that an individual receives from their parents at a locus is randomised with respect to the environment and also to other genes transmitted elsewhere in the genome. This means that any genetic variant that is associated with a biomarker of interest, will be randomised with respect to potential confounding variables. Thus any association between the biomarker-associated variant and a clinical outcome of interest suggests that that biomarker is causal for the clinical outcome. In other words, Mendelian randomisation is like a randomised controlled trial, except that nature does the randomisation, rather than the experimenter.

The first Mendelian randomisation studies of sepsis have begun to appear in the literature.[24],[25] A recent Mendelian randomisation study found evidence that genetic variants that mimicked blockade of the IL-6 receptor (i.e. as would occur with the drug tocilizumab) were associated with decreased risk of sepsis, decreased severity of sepsis and reduced chance of mortality.[24] The implication is that pharmacological manipulation of the

IL-6 receptor and pathway may be worth prioritising for future randomised controlled trials for sepsis. Nevertheless, it is worth bearing in mind that Mendelian randomisation studies involve a number of limitations – most notably that the findings could also be explained by genetic pleiotropy (i.e. the possibility that the variant related to the biomarker of interest is related to the clinical outcome through a biological pathway other than through the biomarker). Thus, the findings from Mendelian randomisation studies will need to be scrutinised using a range of sensitivity analyses, replicated in independent cohorts, and if still looking promising, confirmed in randomised controlled trials. [26]

Gene Expression Studies

Microarray technology also permits genome-wide gene expression profiling, providing a further layer of information in addition to that provided by GWAS. Typically these studies are performed on samples of whole blood from patients and therefore represent the combined expression of genes across many different varieties of blood cells, although it is obviously also possible to focus on specific cell types if steps are taken to purify the samples first (e.g. by flow cytometry). [27] Several studies in this area have identified differential gene expression patterns in patients with sepsis, which may help identify individuals at higher risk of mortality.

In 2010 Tang et al. published a systematic review of microarray studies performed in human patients with sepsis. [28] They identified 12 cohorts consisting of 784 individuals in total with genome-wide expression data. The largest single cohort comprised 176 individuals, with the majority of studies recruiting less than 100 patients. While a consistent finding across the studies was the upregulation of receptors involved in pathogen recognition, the authors failed to observe any other consistent expression pattern relating to changes in the inflammatory response. Transcriptional changes in inflammatory genes appeared to be highly variable, and no repeatable change in the expression of genes involved in cytokine production or other inflammatory mediators was observed.

In 2009, Wong et al. described the results of genome-wide expression profiling using RNA derived from whole blood in 98 paediatric patients with septic shock. [29] They observed just under 7000 differentially regulated genes, and using a hierarchical cluster technique identified 3 subclasses of septic shock. Patients in subclass ‘A’ had a significantly higher sickness severity and a higher mortality rate. Of the genes that appeared to have the strongest predictive ability to identify subclasses, a majority corresponded to signalling pathways in the adaptive immune system and glucocorticoid receptor signalling. Additionally, patients in subclass ‘A’ appeared to have large-scale repression of genes related to zinc biology. The authors subsequently validated their findings in a further cohort of 82 paediatric patients. [30] Of particular interest was the observation that adjunctive corticosteroid treatment was associated with a higher mortality only in the subclass of patients in whom the genes associated with glucocorticoid signalling appeared to be repressed. [31]

Antcliffe et al in a post hoc analysis of 176 patients from the VANISH trial reported that transcriptomic profile at the onset of septic shock was associated with response to corticosteroids. They identified two sepsis response signatures, (SRS1 and SRS 2). Those with the immunocompetent SRS2 endotype had significantly higher mortality when given corticosteroids compared with placebo. [32] Cohen et al. in a nested cohort study of 494 patients from the ADRENAL trial examined the expression of adrenocortical candidate genes. Whilst they reported no association between adrenocortical candidate gene expression and mortality they observed that variations in certain gene expression were associated with time to reversal of shock in response to corticosteroids and may be a mechanism for heterogeneity of treatment response to corticosteroids in septic shock. [33]

One of the largest and most recent studies in adult septic patients is that of Davenport et al. They examined gene expression data from 265 adult patients with sepsis from community-acquired pneumonia and identified two ‘sepsis response clusters’ with over 3000 differentially expressed genes. [34] Patients in the first cluster had significantly higher mortality (14-day mortality 59% vs. 29%). Gene network analysis identified the downregulation of genes associated with the immune response in the first cluster, suggesting that relative immune deficiency might play a role in the outcome of sepsis.

These observations will need to be confirmed in large prospective studies but represent the first description of a subclass of patients with septic shock in whom genetic techniques may predict the response to a specific treatment.

RNA-SEQ

RNA-seq is an emergent technique that uses deep-sequencing technologies. Its aim is to quantify the transcriptome, the complete set of transcripts in the cell. In contrast to microarray methods, which rely upon hybridisation to a set of probes, RNA-seq directly sequences a cDNA library of fragments generated from the RNA sample of interest. It has several key advantages over microarray-based approaches, including a much greater range of expression levels over which transcripts can be detected, and it is not limited to the detection of transcripts from known genomic sequences. [35]

To date, there is limited data from this approach in patients with sepsis and septic shock. [36] A further refinement of this technique is single-cell sequencing, in which the RNA sequence from individual cell types in a tissue can be identified. How this approach may increase our understanding and treatment of sepsis remains to be determined, but early work in the field appears promising. [37]

Epigenetics

Epigenetics describes the study of changes in gene expression that are not a result of modifications in the DNA sequence. [38] Potential mechanisms for epigenetic changes include DNA methylation, non-coding RNAs and modification to histones, the proteins around which the DNA double helix is wrapped. The study of how epigenetic changes may influence sepsis is in its very early stages, [39], [40] but available data suggests this may be a further mechanism for explaining differences in the susceptibility and response to this condition.

Summary

Our understanding of how genetic factors may influence the development and outcome of sepsis has greatly increased over the last few decades, driven by the rapid development of new molecular genetic techniques. However, as our knowledge has increased, so has the appreciation that as a highly complex syndrome, there are unlikely to be simple genetic changes that can serve to inform prognosis or therapy. Nevertheless, continuing research in this field may well yield the hoped for ‘personalised medicine approach’ so essential for a disease characterised by heterogeneity.

Glossary

Adoption study: A type of epidemiological study design where the similarity between parents and their biological offspring is compared to the similarity between parents and their adopted offspring.

Allele: Alternate forms of a gene/SNP.

Candidate gene study: A type of genetic association study where a relatively small number of genetic polymorphisms is investigated in a region of the genome that the investigator thinks is likely to be involved in the trait of interest.

Complex disease/trait: A disease/trait that is caused by many genetic variants of small effects and environmental factors. Most of the common diseases of major public health relevance (including sepsis) are complex diseases. Epigenetics describes the study of changes in gene expression that are not a result of modifications in the DNA sequence.

Gene: A simple definition of a gene is a part of the genome that codes for a protein.

Genetic variant: A part of the human genetic sequence that varies between individuals in the population.

Genome: The entire genetic sequence of an individual.

Genome-wide association study (GWAS): A type of genetic association study where individuals typically have hundreds of thousands of SNPs genotyped across their genomes. GWAS are typically performed using microarray technologies that may not physically capture low frequency/rare genetic variants.

Heritability: The proportion of variation in a phenotype that is due to genetic factors.

Microarray: Comprises a silicon chip (or other medium) containing numerous oligonucleotide probes that are complementary to specific sequences in the genome. Microarrays can be used to assay hundreds of thousands of SNPs or measure gene expression in thousands of genes simultaneously.

Nucleotide: A single unit of DNA consisting of a deoxyribose sugar, a phosphate group and a nitrogenous base.

Population stratification: Refers to the situation in genetic studies where the sample consists of individuals of different ancestries. Population stratification may lead to spurious results in genetic studies and often must be corrected for.

(Statistical) Power: The probability of correctly rejecting the null hypothesis of no genetic association. Genome-wide association studies typically need thousands of individuals to have adequate power to detect true genetic associations.

Sequencing: Sequencing is determining the exact order of the bases in a strand of nucleotides.

Single nucleotide polymorphism (SNP): A single base change in the sequence of the genome that varies across individuals. SNPs are the form of genetic variation that is most often tested in genome-wide association studies.

Transcription: The process by which the DNA sequence is coded into messenger RNA.

Transcriptome: The sum total of all the mRNA molecules expressed from the genes of an organism

Translation: The process whereby messenger RNA is coded into a sequence of amino acids.

Type I error: Refers to the situation where an association is claimed but in fact, no such association really exists. In genetic studies, this may arise from a number of sources including statistical fluctuation, population stratification and the unintended inclusion of related individuals in a genetic analysis of unrelated individuals.

(Classical) Twin Study: This sort of epidemiological study design compares the trait similarity of identical twins (who share all their genes in common) to the similarity between non-identical twins (who share on average half their genes in common). Excess similarity in identical twins compared to the non-identical counterparts provides evidence that a trait has a genetic aetiology and estimates of the trait heritability can be produced.

Whole genome sequencing: Refers to sequencing the entire genetic sequence of an individual. Currently expensive to do.

Healthcare-associated infection

Stuart Dickson

Introduction

The term ‘nosocomial infection’ derived from its classical origins refers strictly to infection acquired in a hospital. With our greater understanding of the complex epidemiology of infection arising in individuals receiving healthcare, this term is increasingly unhelpful, with the term healthcare-associated infection (HAI) being a more accurate descriptor. Infections acquired during the delivery of healthcare may be acquired in community or hospital settings and similarly may first present clinically in either.

HAI is a major problem in hospitals resulting in increased morbidity and mortality. This manifests as an increased length of admission and greater consumption of healthcare resources. The economic impact of HAI varies between healthcare systems; the annual direct costs of HAI in the UK and USA healthcare systems are estimated to be £503 million and $28–45 billion respectively.[1,2]

Epidemiology

Point-prevalence surveys estimate that 6.5% of patients in European acute care hospitals and 3.9% of residents in long-term care facilities have at least one HAI.[3] In the Extended Study on Prevalence of Infection in Intensive Care (EPIC III), an international point-prevalence study performed in 2017, the rate of suspected or proven infection in intensive care unit (ICU) was 54%. 21% of patients had ICU-acquired infection, which is associated with a higher risk of in-hospital mortality than community-acquired infection. [4] Individual risk factors which increase the risk of HAI include being treated in a teaching hospital, increasing age, emergency admission and co-morbidities of cancer, cardiovascular disease, chronic kidney disease and diabetes. Admission to ICU, surgery <30 days prior to admission and a total length of hospital stay for >30 days in the 2 years prior to admission all increased the risk of acquiring HAI. [5] The medical equipment used to facilitate intensive care including intravascular catheters, invasive monitoring devices, cardiopulmonary assist devices, ventilators, urinary catheters and enteral feeding tubes; all contribute to the increased risk of HAI in ICU. In a multi-state point-prevalence study in the United States, device-associated infection (i.e. ventilator-associated pneumonia, catheter-associated urinary tract infection and central catheter-associated bloodstream infection) accounted for 25.6% of HAIs. Surgical site and gastrointestinal infections accounted for 21.8% and 17.1% of HAIs respectively, with 70.9% of gastrointestinal infections being caused by toxin-producing *Clostridium difficile* . [6]

Interaction between patient, organism and the environment

HAI arises as the result of a complex interaction between individual risk factors, the processes of healthcare, the healthcare environment and the pathogen. The healthy host usually lives in symbiotic tranquillity with a wide range of commensal organisms. Antibiotics alter the host flora by suppressing or eradicating susceptible commensal organisms and allowing the overgrowth of bacteria with inherent or acquired antibiotic resistance. Microorganisms such as *Candida spp* will flourish in the presence of broad-spectrum antibiotics, and the resulting overgrowth may result in symptomatic or even invasive candidiasis. Cephalosporin use may encourage the intrinsically resistant but quiescent enterococci to emerge as a problematic organism. Increased exposure to antibiotics in the healthcare environment increases the likelihood of acquiring new colonisation with resistant pathogens. Resistant bacteria flourish in the healthcare environment of the ICU and may be transmitted directly or indirectly from patients, or from contaminated surfaces and equipment, via healthcare staff. Anti-microbial-resistant organisms thrive in the healthcare environment because of local pressures (e.g. antibiotics) or from poor hygiene.

The interpretation of microbiology results in the critically ill patient always requires the clinician to discriminate between colonisation and infection. This requires a multidisciplinary approach, interpreting the clinical evidence together with the diagnostic results from the microbiology laboratory.

A vast range of organisms can cause HAI, but a smaller number of particular organisms cause the majority of infections. It must be emphasised that each hospital and each ICU will have its own local microbiological ecology. Regional, national and international surveys give indications of general trends, but this does not supplant local knowledge.

The individual characteristics of the microorganism are important. These include their resilience in the local environment, ease of transmission and individual pathogenicity. The likelihood of HAI is a product of the interaction between the inherent characteristics of the pathogen and its interaction with numerous host factors which increase susceptibility to infection. Some usually innocuous organisms, such as *Candida* spp. or *Serratia marcescens* , will cause problems only in particularly vulnerable hosts, whereas strains of *S. aureus, Pseudomonas aeruginosa* or *Clostridium difficile* may be intrinsically more virulent and therefore be seen in a broader range of critically ill patients.

The cohorting of sick patients with impaired immunity and the widespread use of broad-spectrum antibiotics make the ICU a particularly high-risk clinical environment for the evolution of multi–drug-resistant pathogens. On discharge from the ICU, patients are typically transferred to various specialty wards for ongoing care. Sub-optimal infection control practice and poor control of antibiotic use in the ICU will have potentially serious consequences for other areas of the hospital, where ICU survivors are typically nursed alongside the general patient population.

Causative organisms

The range of organisms causing HAI in the ICU has changed over the past three decades. The proportion of HAIs caused by methicillin-resistant

Staphylococcus Aureus (MRSA) and *Pseudomonas spp* have significantly decreased, whilst the prevalence of increasingly resistant gram-negative bacteria has increased. [4] , [7] , [8]

Pseudomonas Aeruginosa

P. aeruginosa is a gram-negative bacteria and is one of the most common pathogens associated with healthcare-associated pneumonia (HAP). It can readily persist in a range of environmental conditions. Due to its large genome, it is intrinsically resistant to a significant number of commonly used antibiotics, rendering therapy challenging. It is of clinical significance in patients suffering from chronic lung disease (such as cystic fibrosis, chronic obstructive pulmonary disease [COPD] or bronchiectasis), where colonisation of the respiratory tract leads to recurrent infections with increased morbidity and mortality. Patients with burns and surgical site infections are also susceptible to *Pseudomonas* infections. Resistance may develop in a number of ways and so can engender a very broad spectrum of resistance, making treatment challenging. Pseudomonal infection is associated with adverse outcomes in the critically ill and, in common with another extended-spectrum beta-lactamase (ESBL) producing gram-negative organisms, multidrug-resistant pseudomonal strains are growing in number. [9] , [10]

Acinetobacter spp

Acinetobacter spp has become a major cause of HAI in ICUs across the world. Its ability to resist desiccation and exposure to disinfectants underpins its ability to persist in the environment. It is often multi-drug resistant and, although historically sensitive to carbapenems, it is increasingly seen to be resistant even to these agents with some organisms sensitive only to colistin, polymyxins and tigecycline. It is a common cause of HAI in the ICU and is frequently implicated in outbreaks of infection. Once carbapenem resistance is acquired, treatment options are limited and should be guided by infection experts with knowledge of susceptibility patterns. [11] , [12]

Coagulase-Negative Staphylococci (CoNS)

CoNS are gram-positive bacteria with generally low virulence. They are common skin commensals with a predilection for causing infection associated with indwelling devices. Their resilience to treatment is in part due to the production of a biofilm on affected devices. They are intrinsically resistant to multiple classes of antibiotics but are usually sensitive to glycopeptides. As glycopeptide resistance patterns increase, agents such as linezolid, daptomycin and tigecycline may be useful; however, resistance to any of these drugs may arise. [13]

Methicillin-Resistant Staphylococcus Aureus (MRSA)

S. aureus is a virulent pathogen causing a wide range of infections. It has a plethora of virulence factors with endogenous toxins giving rise to most of the clinical syndromes seen, such as invasive skin and soft tissue infections, food poisoning and pneumonia. Methicillin resistance was first noted in the early 1960s and, although rates between countries and ICUs vary considerably, there was an inexorable rise in its prevalence in most countries until the late 1990s. MRSA is highly transmissible in the ICU environment with colonisation of both healthcare workers and patients driving high transmission rates and giving rise to frequent outbreaks. Glycopeptides are currently commonly used to treat invasive MRSA infections but, as ever, source control is of paramount importance. Newer anti-MRSA agents include linezolid, tigecycline and daptomycin. [14] Anti-MRSA cephalosporins have also been developed (ceftaroline, ceftobiprole) but their role in clinical practice remains unclear. Rates of MRSA infection in ICUs in the United Kingdom since 2006, have fallen by 97% following the successful introduction of national comprehensive multi-component infection control surveillance and intervention campaigns. [15]

Clostridium Difficile

Clostridium difficile-associated diarrhoea (CDAD) was first recognised as a clinical problem following the administration of certain antibiotics, in particular clindamycin. It is now clear that in the critically ill, CDAD can emerge following the clinical use of almost any broad-spectrum antibiotic. *C. difficile* produces toxins which cause tissue injury leading to diarrhoea and colitis. Antibiotic use, environmental contamination and transmission by healthcare staff are all modifiable risk factors increasing the risk of CDAD in the ICU.

Treatment with oral vancomycin or fidaxomicin is now preferred to metronidazole for uncomplicated disease. In severe disease accompanied by ileus, parenteral metronidazole should be administered in addition to oral vancomycin. [16] Total colectomy with end-ileostomy has traditionally been the surgical procedure of choice for fulminant colitis. However, loop ileostomy and anterograde washout may offer an alternative colon-preserving approach in suitable patients. [17]

Candida spp

Candidaemia is the fourth most common bloodstream infection in the United States and the sixth most common in Europe. [18] The prevalence of individual *Candida* species is highly variable in different healthcare settings, but *Candida albicans* is the most common. The widespread use of azole anti-fungal drugs may have influenced the relative increase in *C. glabrata* and *C. krusei* species, which are intrinsically azole resistant. *C. auris* and *C. parapsilosi* s have emerged as difficult pathogens in the ICU with multidrug resistance and persistence in the environment. [19, 20] Definitive diagnosis of candidaemia is by blood culture, but presumptive diagnosis of invasive candidiasis is suggested by unexplained fever in a patient with risk factors for invasive candidiasis with evidence of colonisation by *Candida sp* at non-sterile sites. [21] Whilst the choice of empirical anti-fungal treatment for possible or probable invasive candidiasis should be guided by knowledge of local fungal ecology, treatment of confirmed invasive candidiasis or candidaemia should be led by culture and sensitivities.

Anti-microbial Resistance and Mechanisms

The emergence of anti-microbial resistance (AMR) is a natural evolutionary response to anti-microbial exposure. Globally, multiple interrelated factors are increasing the prevalence of AMR microorganisms, predominantly arising from the use of anti-microbials in humans and agriculture and the pollution of the environment. The increasing challenge to health care of AMR, and the subsequent lack of access to effective anti-microbials, is of global concern. [22]

There are a range of mechanisms which can be involved in the development of antibiotic resistance [22] :

1. Enzymatic inactivation of drug.
2. Altered drug-binding site.
3. Decreased uptake of drug, either by decreased penetration or by up-regulated efflux pumps.
4. Bypass pathways.

Resistance to any given anti-microbial class may occur via multiple pathways, with a single bacteria capable of using a range of mechanisms to survive the effect of an antibiotic. [23]

The main mechanism of β-lactam resistance relies on the destruction of β-lactam antibiotics by the action of β-lactamase enzymes. More than a thousand different beta-lactamases have been described.

ESBL enzymes carried by a broad range of gram-negative bacteria have seen an eight-fold increase in carriage rates in healthy individuals over the past 20 years. [24] ESBL-positive pathogens are typically associated with resistance to fluoroquinolones and extended-spectrum cephalosporins and are significantly associated with increased mortality. [25] As carbapenems have been increasingly used for the treatment of ESBL-positive gram-negative infections, the co-carriage of carbapenemase enzymes has been increasingly seen.

Carbapenemases are a family of beta-lactamase enzymes many of which demonstrate resilience against all commercially available beta-lactamase inhibitors. Carbapenemase-producing Enterobacteriaceae (CPE) were first described in the 1980s and have become increasingly prominent globally over the last 20 years. The Enterobacteriaceae implicated tend to be *E. coli* and *Klebsiella pneumoniae* , but the range of organisms capable of producing these enzymes is expanding. The organisms are typically resistant to carbapenems, and frequently many other antibiotic classes too, thus making treatment options extremely limited. As such these organisms are associated with increased morbidity and mortality and have the capacity to cause outbreaks in the ICU. Treatment should be tailored to individual clinical circumstances and must be guided by culture results and susceptibility patterns. Colistin, tigecycline, aminoglycosides and novel β-lactam/β-lactamase inhibitor combination therapies (e.g. meropenem/vaborbactam and ceftazidime/avibactam or aztreonam/avibactam) are options which may be used in combination for the treatment of severe invasive CPE infection. [26]

Types of HAI

HAI can occur as infection at single or multiple sites. Single or multiple pathogens may cause infection simultaneously or sequentially at one or more sites. Clinical assessment and careful interpretation of laboratory culture results are required to ensure clinically appropriate treatment is instigated at the correct time.

1. Central line-associated bloodstream infection (CLABSI)

Colonisation of the central venous catheter (CVC) is common, and it is likely that this is a precursor of infection by virtue of the development of a biofilm. Risk factors for CLABSI [27] include:

- Prolonged hospitalisation before insertion of CVC
- Prolonged duration of catheterisation
- Heavy microbial colonisation of the catheter hub
- Multi-lumen catheters
- Concurrent catheters

- Neutropaenia
- Body mass index >40
- Reduced nurse-to-patient ratio in ICU
- Parenteral nutrition
- Substandard catheter care

Definitions [28]

1. *Colonised catheter:* growth of greater than >15 CFU (semi-quantitative) or $>10^3$ CFU/mL (quantitative) from a proximal or distal catheter segment in the absence of accompanying clinical symptoms and signs.
2. *Catheter-related bloodstream infection:*
   a. The occurrence of a bacteraemia or fungaemia during the 48-hour period surrounding catheter removal (or a suspected diagnosis of CLABSI when the catheter has not been removed).
   b. And either:
      i. A positive culture with the same microorganism from either the insertion site or a catheter culture $>10^3$ CFU/mL.
      ii. Positive central and peripheral blood cultures with the same microorganism, with a central/peripheral ratio of >5, or a central/peripheral blood culture differential time to positivity of >2 hours.

Microorganisms Associated with CLABSI

The organisms involved in catheter-related sepsis are influenced predominantly by the patient’s endogenous flora. There is a 25% incidence of coagulase-negative staphylococci (CoNS) related infections, which are increasingly recognised as pathogens due to their ability to form biofilms on prosthetic material. A biofilm is a three-dimensional matrix of extracellular polymeric material (slime) that allows bacteria to live in communities. These are important owing to their increased resistance to anti-microbials and strong adherence to prosthetic material. *S. aureus* and *Candida* spp. can cause a significant CLABSI with a high risk of metastatic seeding of infection to other organs, such as the eyes and heart valves. Gram-negative pathogens predominate in patients with haematological malignancies, and *Pseudomonas sp* is frequent in burn patients.

Treatment of CLABSI

The most important aspect of managing vascular access device infection is to consider removal of the device if infection is present either locally or systemically. [29] Anti-microbials after catheter removal are recommended with the duration being dependent upon the organism. *Candida* spp. and *S. aureus* require a minimum of 14 days to prevent recurrence or later morbidity. Guidewire-assisted catheter exchange is not routinely recommended for the critically ill. Whilst salvage therapy with antibiotics for infected lines may be considered in other clinical settings where future vascular access is perceived to be anatomically difficult, it is not generally recommended in the ICU setting.

Prevention

There are a number of key preventative strategies which should be routinely employed to minimise the risk of catheter-associated infection. CVCs (and similar devices) should be inserted under maximal aseptic conditions (including handwashing, skin preparation, sterile gown, sterile gloves, cap and mask). The preferred site of CVC insertion with respect to minimising the risk of infection remains unclear due to the age and quality of evidence available. Skin antisepsis with 2% chlorhexidine is preferred. Chlorhexidine-impregnated dressings should be used to cover the insertion site and should not be replaced routinely before 7 days unless soiled. CVCs should only be accessed (drug administration and blood sampling) using a full aseptic technique. Administration sets in continuous use do not need to be replaced more frequently than every 7 days [30] unless they are used for blood or total parenteral nutrition (TPN). CVCs should not be routinely replaced to prevent infection but should be removed when no longer clinically necessary. [28]

2. Catheter-Associated Urinary Tract Infection (CA-UTI)

CA-UTIs are infections that arise in the urinary tract because of the presence of a urinary catheter. CA-UTIs represent approximately 9% of all HAIs. [6] In the ICU, the most effective strategy to reduce the incidence of CA-UTI is to remove the catheter when it is no longer clinically necessary. The use of strict asepsis on insertion of the urinary catheter, the maintenance of a closed catheter drainage system and the use of chlorhexidine washes are all effective strategies in reducing the incidence of CA-UTI in the ICU. [31] , [32]

3. Surgical Site Infection (SSI)

ASSI is an infection arising at or near an operative site within 30 days of surgery, or within 90 days if the surgery involves prosthetic material. SSIs are common, representing 21.8% of all HAIs in a US point-prevalence study [6] and occurring in up to 11% of all surgical procedures. [33] SSIs may arise due to contamination of the surgical site at the time of surgery or subsequent colonisation and infection of the wound in the post-operative period. [34]

Clean operating theatres, good operating techniques and thorough asepsis, both in the theatre and postoperatively, are important. Strategies such as pre-operative decolonisation with intra-nasal anti-staphylococcal agents, using electric clippers with single-use tips for hair removal, use of chlorhexidine gluconate and alcohol-based skin preparation, maintaining normothermia during surgery, good peri-operative glycaemic control and use of negative pressure wound therapy are all associated with a lower risk of post-operative SSI. [35]

The aim of administering antibiotics prophylactically at the time of surgery is to reduce rates of SSI in the post-operative period. Antibiotic prophylaxis guidelines which take account of local resistance patterns should be readily accessible and be followed. Effective prophylaxis requires an antibiotic:

- with a spectrum that covers the most likely organisms
- to be given prior to contamination (30–60 minutes pre-operatively)
- at peak dosage at the time of contamination.

A single dose should suffice, although a second dose is recommended if the procedure extends beyond 4 hours, or a significant amount of blood loss occurs.

Prolonged administration of antibiotics in the post-operative period increases the chance of antibiotic resistance, unnecessarily exposes the patient to the adverse effects of the antibiotic and encourages colonisation and late infections with resistant organisms.

Surgical prophylaxis for patients with known carriage of multi-drug resistant organisms requires a tailored approach and should be discussed with infection specialists prior to surgery. With grafts, mesh or prostheses the morbidity from infection is so great as to justify using prophylaxis even if the evidence is marginal.

4. Healthcare-Associated Pneumonia (HAP)

HAP is the most common HAI, a subset of whom are those who develop ventilator-associated pneumonia (VAP) having received invasive mechanical ventilation during critical illness for at least 48 hours. There remains no gold standard for the definition of VAP, therefore interpreting research on prevention, treatment and clinical outcomes is fraught with difficulty. VAP reportedly occurs in 5% to 40% of ventilated patients, with rates varying considerably between countries. [36]

In the development of VAP, there are several postulated mechanisms, including aspiration from the nasopharynx, local spread and haematogenous spread of infection. In hospitalised individuals, the flora of the nasopharynx changes rapidly as they acquire colonisation with a range of organisms from the healthcare environment, usually gram-negative species. The risk of micro-aspiration (and occasionally macro-aspiration) of oropharyngeal secretions and gastric contents is increased by the unconscious state, the presence of a nasogastric tube and by endotracheal intubation. Patient factors predisposing to VAP include the severity of the acute illness, chronic disease, diabetes, immunosuppression, advanced age, recent surgery to the thorax or abdomen, neurological injury resulting in loss of consciousness and previous intubation or bronchoscopy. Environmental factors include broad-spectrum antibiotics and their prolonged use, environmental pathogens, bacterial properties such as the ability to adhere to surfaces, cross-infection by healthcare staff and equipment, frequent ventilator tubing changes and foreign bodies such as nasogastric tubes. The benefits of stress ulcer prophylaxis in the ICU increase the risk of VAP and must be weighed against the risk of stress ulceration in the ventilated patient. [37] Whilst long-term use of proton-pump inhibitors increases the risk of *C. difficile* infection in the wider population of hospitalised patients, there is less evidence that acute prescriptions for stress ulcer prophylaxis in ICU have a similar effect on *C. difficile* infection rates. [38], [39]

The general criteria for diagnosis of VAP are the clinical signs of a lower respiratory tract infection, purulent sputum, rising inflammatory markers, radiological evidence and positive cultures from sputum or blood. These criteria are non-specific, and obtaining deep respiratory samples with quantitative analysis remains the preferred method of diagnosis. [40] Over-reliance on clinical assessment and endotracheal aspirates may result in over-treatment of patients with suspected VAP. [41] Deep respiratory samples can be obtained using different techniques including protected brush specimens, bronchoalveolar lavage (BAL) and protected BAL.

Early-onset VAP, occurring between 48 hours and 5 days following intubation, may be more likely due to community pathogens, such as methicillin-sensitive *S. aureus, Streptococcus pneumoniae* and *Haemophilus influenzae* . In late-onset VAP (after 5–7 days following intubation), multidrug-resistant organisms, such as MRSA, *P. aeruginosa* , *Acinetobacter baumannii* and *S. maltophilia* , occur more commonly.

The prevention of VAP in ICU has traditionally been approached utilising bundles of care that aim to reduce the risk of aspiration, cross-infection and contamination of respiratory devices. Many long-standing assumptions about how best to reduce the risk of VAP have been challenged in recent years with emerging, sometimes contradictory, evidence. Strategies involving oral care with chlorhexidine [42] can no longer be routinely recommended for preventing VAP. Similarly, novel endotracheal tubes with subglottic secretion drainage, with ultra-thin polyurethane cuffs or with continuous cuff pressure monitoring devices cannot be routinely recommended.[43]

Generally accepted strategies to reduce the risk of VAP[44] include:

- use of non-invasive ventilation or high-flow nasal oxygen systems, where possible, to avoid invasive ventilation
- undertaking daily sedation holds and spontaneous breathing trials to assess for readiness to extubate
- limiting antibiotic use
- changing ventilator circuits only when clinically indicated
- removing nasogastric tubes when not required
- utilising the semi-recumbent position as much as possible to avoid prolonged nursing in the supine position

The strategy of utilising short courses of antibiotics to prevent VAP in specific clinical groups aims to deliver clinical effects without detrimental changes in local microbiological ecology and resistance patterns. A three-day course of nebulised amikacin in patients who have been ventilated for more than three days resulted in a reduction in VAP over the following 28 days from 22% to 15% in a single double-blind randomised controlled trial.[45] A two-day course of amoxicillin-clavulinic acid in patients admitted to ICU having survived out-of-hospital cardiac arrest resulted in a reduction of early VAP from 34% to 19%.[46] Definitive evaluation of the efficacy of these approaches will require larger clinical trials but show promise in targeting preventative antibiotics to specific patient groups to good clinical effect whilst possibly avoiding undesirable effects and adverse consequences.

The use of probiotics as a strategy to reduce the incidence of VAP in ICU has been explored with promising results.[47] A probiotic is a non-pathogenic microorganism which is administered in an attempt order to reduce the risk of translocation of pathogenic bowel flora across damaged bowel mucosa in the critically ill patient. However, as yet there is insufficient evidence to recommend the routine use of probiotics in ICU.

In the treatment of VAP, the use of inappropriate antibiotics leads to an increased mortality so current trends are towards initial broad-spectrum antibiotics followed by reassessment and de-escalation to drugs with a narrower spectrum of action.[48], [49] As the spectrum of resistance grows globally, it is highly likely that it will be increasingly difficult to apply this initially broad-spectrum empirical treatment effectively, especially in cases of late-onset VAP. Surveillance of current colonisation, awareness of an individual ICU’s ecology and targeted treatment should guide treatment decisions and replace empiric regimens in this clinical situation. Duration of treatment depends upon both the nature of the pathogen and the clinical syndrome. Uncomplicated pneumonia may be treated with 5 to 7 days of antibiotic therapy.[50], [51] Longer courses will be required in the presence of empyema or pulmonary abscess.

Infection prevention and control

Infection prevention and control (IPC) is a practical, evidence-based approach to prevent patients and healthcare workers from being harmed by avoidable infections. Good IPC practice is essential in minimising HAI.[52] Healthcare facilities have a statutory obligation to manage and implement processes to control infection and promote cleanliness. Each hospital employs an IPC team that provides guidance to ensure all healthcare staff are aware of and discharge their responsibilities to prevent and control infection. Appropriate use of anti-microbial therapy and active systems to promote good anti-microbial stewardship are cornerstones of good IPC practice.

The most important aspects of preventing HAI are simple hygiene measures, such as hand washing, and promoting a culture where IPC processes are enshrined in everyday working practice. Chlorhexidine gluconate bathing is routinely performed in the ICU alongside MRSA screening startegies and the application of nasal mupirocin in order to reduce colonisation with MRSA.[53] Given concerns of mupirocin resistance, the antiseptic iodophor administered nasally has been studied as an alternative strategy but was found to be inferior to the standard approach of chlorhexidine bathing and nasal mupirocin.[54] There are several further strategies which may have a role in reducing the risk of HAI, particularly in the ICU. These include surveillance and screening, quarantine and isolation, selective decontamination of the digestive tract (SDD) and anti-microbial stewardship.

Surveillance and Screening

Routine culture surveillance of both patients in the ICU and their environment provides information on the organisms currently prevalent and is a useful tool in guiding management in individual cases and when unexpected clusters or outbreaks of infection occur. Molecular typing of pathogens is a vital tool in confirming cross-infection and gives the clinician the ability to track the organism during an outbreak and understand the epidemiology.

Routine screening of patients allows the identification of multidrug-resistant organisms and therefore allows enhanced barrier precautions and targeted interventions to be implemented. MRSA, CPE, vancomycin-resistant Enterococci (VRE) and *Acinetobacter baumanii* are organisms often targeted by screening processes.

Isolation

Although physical barriers undoubtedly reduce the risk of cross-contamination between patients, isolation can be hazardous as it may result in lower-intensity care. Modern ICU design seeks to balance the need to isolate with the ability to monitor critically ill patients effectively. The relative risks of isolation versus patient management in a multi-occupancy clinical area need to be actively assessed in each case. Isolation using side rooms with or without negative pressure may be utilised to reduce the risk of transmission of infection from patients colonised or infected with multi-drug-resistant organisms or with potentially infectious diarrhoea. Isolation facilities may also be used as quarantine facilities for patients repatriated from other healthcare facilities (pending results of microbiological screening), where the risk of acquiring colonisation or infection with difficult-to-treat multi-drug resistant organisms is perceived to be high (e.g. CPE).

Selective Decontamination of the Digestive Tract

SDD is a preventive strategy which through the use of non-absorbable topical antibiotic agents administered to the oropharynx and upper GI tract of the ventilated patient, with or without the concomitant administration of a parenteral antibiotic; seeks to reduce the incidence of bloodstream infections, VAP and associated mortality. Despite extensive study and repeated review of the accumulating evidence base over the past four decades, its place in clinical practice in the ICU remains controversial. Meta-analyses of the use of SDD in ventilated patients in ICU, suggest that the incidence of both VAP and in-hospital mortality rates are lower.[55],[56] However, recent large clinical trials of SDD in Europe and Australasia demonstrated no difference in the rate of bloodstream infections or hospital mortality respectively.[57],[58] Concerns continue with respect to the quality of clinical evidence and its generalisability across healthcare systems characterised by different microbiological ecology and antibiotic prescribing practices. These factors, together with concerns related to the theoretical risk of generating worsening anti-microbial resistance patterns, remain significant obstacles to the adoption of SDD in mainstream clinical practice in the ICU.

Antibiotic Stewardship

Antibiotic stewardship describes the range of activities which together aim to optimise and ensure the appropriate use of anti-microbials by promoting the selection of the right anti-microbial, at the correct dose for the appropriate duration required. The burden of AMR is driven by multiple factors including inappropriate antibiotic use. Poor management of anti-microbials in the ICU can drive high rates of AMR not only in the ICU but across the whole hospital community. Anti-microbial steward programmes (ASPs) in the ICU not only reduce the rates of resistance but also reduce the duration of ventilation, days of antibiotic use and associated healthcare costs.[59] Prospective audit and feedback are key elements of ASPs. The use of all anti-microbials should be reviewed daily, ideally in association with an infection specialist. Empirically prescribed broad-spectrum antibiotics should be reviewed as soon as culture results are available and stopped or rationalised to narrower spectrum anti-microbials whenever possible.

Fungal infection

Alastair Craig Carr

The incidence of invasive fungal infection (IFI) in the critically ill population is increasing. Care of increasingly debilitated patients, increased broad-spectrum antibiotic and immunomodulatory therapy use and, most recently, COVID-19 are associated with rising nosocomial IFIs. Fungi may also cause poisoning, allergic and inflammatory conditions necessitating ICU admission.

Candida species were the fourth (USA[1]) and sixth (European[2]) commonest isolates from blood cultures in two large studies. Candidaemia incidence ranges from 0.2 to 34/1000 ICU patients in different global sites. Both primary and opportunistic fungal infections are associated with high mortality, despite appropriate therapy, when systemic rather than local infection occurs (Table 19.1).

Table 19.1

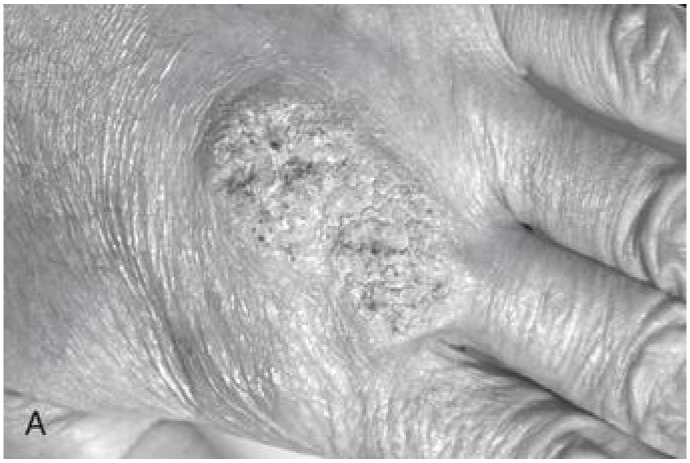
Case fatality rate of different invasive fungal infections assuming optimal treatment of infection and underlying illnesses

FUNGAL INFECTION	CASE FATALITY RATE	COMMENTS
Invasive candidiasis	30%–50%	Trend from albicans to others likely due to fluconazole prophylaxis selecting out more resistant species
Invasive aspergillosis	30%–70%	Higher mortality in COPD than haematology patients. Increased incidence during COVID-19 pandemic
Pneumocystis pneumonia	10%–50%	Higher mortality in non–HIV related cases may relate to later diagnosis and less vigilance
Cryptococcal meningitis	10%–30%	C. neoformans commoner in AIDS or the immunosuppressed, whereas *C. gattii* may also cause primary IFI
Mucormycosis	20%–80%	Higher mortality in pulmonary, cerebral and disseminated disease vs. rhino-ocular
Disseminated histoplasmosis	10%–20%	May require life-long therapy; high relapse rate, especially in chronic respiratory disease

Late diagnosis and treatment worsen outcomes. Unfortunately, diagnosis is often challenging:

- Cultures may take weeks to isolate certain pathogenic fungi and sensitivity may be lower than 50% in proven invasive disease.
- Serological testing often lacks sensitivity and specificity.
- Radiological changes may develop late in the disease process.
- Matrix-assisted laser desorption/ionisation time-of-flight (MALDI-TOF) mass spectrometry can be used to speed typing only if positive cultures are obtained. [3]

Rapid (<24 hours), sensitive and specific analyses such as pan-fungal real-time polymerase chain reaction (PCR) [4] and T2-candida, [5] are establishing their utility but are not widely available. Cutaneous lesions are features of many IFI and lend themselves to biopsy and diagnosis if recognised (Fig. 19.1).



The three-part clinical visual is labelled A, B, and C. Part A shows a dorsal view of a hand with a raised, irregularly bordered lesion that is crusted and scaly in appearance, surrounded by wrinkled skin. Part B shows a close view of the central face near the nose and upper lip, with multiple lesions of varying size and contour, including a prominent cratered lesion below the nasal opening and other rounded lesions with central depressions. Part C shows a view of the cheek and upper lip region, displaying numerous small, dome-shaped lesions scattered across the area, some with central puncta. The visual presents surface-level dermatological abnormalities with variations in texture and morphology across all three parts.

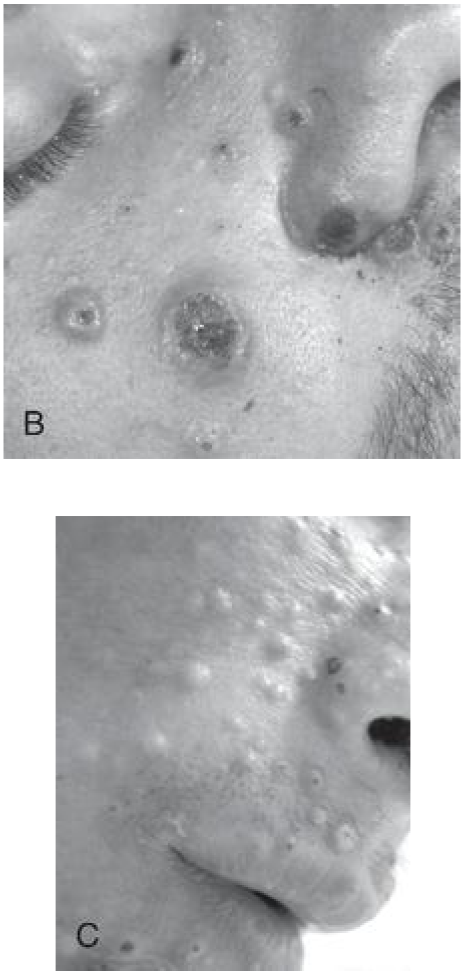


FIG. 19.1 **(A) Blastomycosis (Gilchrist disease) showing progression of initial subcutaneous nodules into a larger ulcerated crusting lesion.** ***(Reproduced under licence from Getty Images.)*** (B) Cryptococcosis showing characteristic raised skin lesions with rolled edges and central necrosis and scabbing. *(Reproduced under licence from Getty Images.)* (C) Penicillinosis: raised papules with a central necrotic area similar to molluscum contagiosum. (Reproduced with permission under open access from Wong SYN, Wong KF. Penicillium marneffei infection in AIDS. *Patholog Res Int* . 2011;764293. doi:10.4061/2011/764293.)

Classical markers for infection are less reliable in fungal than bacterial infections. Meta-analysis suggests that a mildly elevated procalcitonin (PCT) (0.5–2 ng/mL) in the presence of clinical signs of sepsis may have merit in indicating invasive fungal infection. [6] CRP's utility is less certain with a spectrum of values (including normal) being reported even in proven IFIs.

Given these limitations, understanding fungal infections, their incidence, characteristics and the predisposing risk factors remains critical to early diagnosis, appropriate management and improving outcomes.

Background Mycology

Fungi are complex eukaryotic organisms with a cell membrane and internal organelles. While a few, such as *Candida* , largely exist in unicellular states (yeasts), most exist in multicellular (mould) states and expand through multicellular hyphal growth. Some species are dimorphic, existing in either unicellular or multicellular states. Controversy exists around classification; certain fungi are classified as yeasts by some experts and moulds by others.

A network of interdigitating hyphae is known as a mycelium. A multicellular mould with its mycelium is often described as a ‘colony’, but is more usually considered a single microorganism, not a collection of discrete microorganisms.

Moulds reproduce through the production of mononuclear or multinuclear, unicellular or multicellular spores along their hyphae. The spores break off, travel through air or fluid and form new multicellular moulds distinct from their point of origin. Hyphae also secrete:

- lytic enzymes that break down complex organic structures into simpler nutrient compounds
- mycotoxins that inhibit the growth of competitor microorganisms… these may be beneficial or harmful to man (Table 19.2).

Table 19.2

Examples of potential harmful and beneficial effects of different mycotoxins relevant to ICU

FUNGAL MYCOTOXIN	SOURCE	EFFECTS
Aflatoxins	Moulds on stored grains, seeds and nuts	Carcinogenic in long-term; acute hepatotoxicity and neurotoxicity with higher doses
Amatoxins	Death-cap mushrooms	Irreversible RNA polymerase inhibition with multi-organ failure 12-48 hrs post ingestion
Ergot alkaloids	Claviceps purpura moulds on cereals	Convulsions, psychosis, vasoconstriction and peripheral gangrene
Penicillin	Variety of blue-green moulds on fruit and cheeses	Use as antibiotics inhibiting peptidoglycan production in bacterial cell walls
Psilocin/psilocybin	Polyphyletic ‘magic mushrooms’	Psychotropic effects, including hallucinations and psychosis
Trichothecenes	Moulds on grains (e.g. maize oats) or in damp houses	Inhibition of ribosomal protein, RNA, DNA synthesis leading to MOFS – used as chemical weapon

Yeasts are generally considered less invasive than moulds. Nonetheless, their resistance to anti-fungal therapies is rising with the wider use of prophylaxis in high-susceptibility populations, and the mortality of invasive disease is high.

50,000 to 5,000,000 different fungal species are estimated to exist, depending on the methodologies of classification. The Centre for Disease Prevention and Control estimates 1.5 million fungal species exist with around 600 recognised as human pathogens.

Invasive Fungal Infections

There are two main categories of IFI:

1. **Primary mycoses** occur in immunocompetent patients. These are endemic in geographical locations where the spores are abundant. The infecting agent has innate virulence that overcomes normal host defences.
2. **Secondary or opportunistic mycoses** have less innate virulence than primary mycoses but occur in patients with increased susceptibility or impaired immunity. General debility, cancer, malnutrition, immunosuppressive drugs, burns, HIV, broad-spectrum antibiotics and diabetes all increase susceptibility.

Treatment Options

Pharmacological treatment of most IFI is largely limited to four classes of agents. Removal of infected medical devices and surgical excision of lesions is often necessary for disease control.

1. **Polyenes,** effectively amphotericin B presentations, bind to ergosterol in the fungal wall causing damage and cell death.
2. **Azoles** (imidazoles and triazoles) inhibit ergosterol synthesis in the fungal wall. Usually fungistatic, these occasionally exhibit organism-dependent fungicidal activity too (e.g. voriconazole in *Aspergillus*).
3. **Echinocandins** inhibit β-glucan synthesis, leading to cell wall instability. These are fungicidal for many yeasts and fungistatic for *Aspergillus* .

4. **Flucytosine** is converted to 5-fluorouracil within yeasts and incorporated into RNA there. Efficacy is much better in yeasts than in moulds.

Certain IFIs have alternative or additional therapeutic options. Folic acid inhibition is employed in managing pneumocystosis. Adjuvant interferon-γ is being investigated for invasive candidiasis and aspergillosis management. [7] Adoptive T-cell therapy is being assessed for the prevention of invasive aspergillosis in stem-cell transplant recipients. [8], [9]

The site of infection is important when selecting appropriate anti-fungal therapy. For example, caspofungin has minimal renal excretion and poor efficacy in treating renal tract infection, whereas amphotericin and fluconazole enjoy good efficacy.

Primary mycoses

There are five main primary mycoses. Four (not cryptococcus) are dimorphic pathogens.

1. **Blastomycosis** (Gilchrist disease) is caused by blastomycoses dermatitidis found largely in the soil in North America. [10] While not transmissible from dogs to humans, dogs are susceptible and often exhibit symptoms ahead of their owners during outbreaks. Primary infection is usually pulmonary. However, wound inoculation is also described. Initial infection may be asymptomatic or cause myalgia, malaise, fever and arthralgia. Later, cough, pleurisy, haemoptysis and acute respiratory distress syndrome (ARDS) may develop. Granulomas form at the initial site and then spread haematogenously in 50% of patients. Skin, bone, prostatic, epididymal and testicular infections are common. Central nervous system (CNS) infection occurs in around 10% of disseminated cases.
   Untreated, disseminated blastomycosis mortality exceeds 80%. Early recognition is difficult as symptoms are non-specific. Even in established diseases, symptoms of night sweats, weight loss, cough

and respiratory failure may be mistaken for malignancy or tuberculosis. Similarly, skin and oropharyngeal lesions (see Fig. 19.1A) can be mistaken for carcinomas. The detection of fungi in skin lesions or sputum requires specific staining; the thick capsule evades routine stains. Culture commonly takes 4 to 6 weeks to yield positive results.

Treatment with amphotericin is preferred in severe disease and immunocompromised patients. Courses of 12 months may be required for cure. Itraconazole has proven efficacy in moderate disease and as step-down therapy from amphotericin. Case reports suggest reasonable efficacy for voriconazole and posaconazole but not fluconazole. Echinocandins have poor efficacy in vitro and are not recommended.

2. **Coccidioidomycosis** is caused by *Coccidioides immitis* and *Coccidioides posadasii* , endemic in regions of North America. Infection results from inhalation of spores or wound inoculation. 65% of primary infections are asymptomatic; the rest develop fever, headache and symptoms of respiratory tract infection. Immunological sequelae distant from the primary site may present as erythema multiforme or nodosum and arthralgia (Joaquin Valley Fever). Chest X-ray (CXR) may show patchy infiltration, lobar pneumonia or effusions. ARDS can occur. Around 5% of patients develop chronic pulmonary infection with cavitation.

   1% of patients develop disseminated coccidiodomycosis with granulomatous lesions of skin, bone, joints and meninges being commonest. Disseminated disease has high mortality and is often diagnosed late in non-endemic areas where suspicion is low. Travel to North America and occupational, agricultural exposure should be sought in the history.

   Amphotericin B is recommended to treat disseminated disease. Localised disease can be managed with triazoles or imidazoles but not echinocandins.
3. **Cryptococcosis** as a primary infection is usually associated with the encapsulated yeast *Cryptococcus gattii* rather than *Cryptococcus neoformans* . Both are covered later under opportunistic infections.

4. **Histoplasmosis** is caused by *Histoplasma capsulatum* found throughout Africa, Indonesia, Australasia, the North American Midwest and Central and South America. [11] Some adult populations evidence almost ubiquitous prior exposure on serological testing. Spores from soil and bird droppings are inhaled and invade pulmonary macrophages, divide and result in granuloma formation. Pulmonary disease may run a self-limiting course, or disseminate via the bloodstream and reticuloendothelial systems, causing lymphadenopathies often with hepatic, splenic, gastrointestinal and even CNS involvement. 90% of pulmonary cases are asymptomatic, not requiring treatment. Symptomatic patients experience non-specific malaise, headaches, fever, myalgia and occasionally arthralgia. Immune-related erythema nodosum or multiforme may be seen during initial pulmonary infections, while infected papules and mucosal ulceration (see Fig. 19.1B) develop only in disseminated disease. Dyspnoea, chest pain and haemoptysis may occur. Pre-existing respiratory disease increases susceptibility to chronic pulmonary histoplasmosis.

   Amphotericin B is the agent of first choice, azoles can be used in less severe disease. Untreated, mortality of disseminated disease is around 80%.
5. **Paracoccidiodomycosis** (South American Blastomycosis) is caused by *Paracoccidioides brasiliensis* and *lutzii* . It is largely confined to South and Central America. [12] Invasion occurs via the lungs, where it may cause (usually lobar) pneumonia, pleurisy or remain asymptomatic before spreading to involve skin, mucous membranes, lymphatics, bone and meninges.

   Acute and subacute forms are both associated with lymphadenopathy, fever, malaise and anorexia. These are normally self-limiting and resolve over time. Respiratory symptoms, skin and mucous membrane lesions are rare in acute cases but are common in chronic disease.

   Mortality is high without treatment; 50% of chronic disease progresses to pulmonary fibrosis and 5% develop pulmonary hypertension and cor pulmonale.

Where affordable, itraconazole is the treatment of choice for moderate disease and amphotericin B for severe and refractory cases.[13] Sulphonamides were once the mainstay of therapy being inexpensive compared to azoles and amphotericin B in endemic areas. Maintenance of azole therapy lasting several years is required to achieve eradication, and relapse is common. Echinocandins are not recommended.

Opportunistic mycoses

There are six main classes of opportunistic mycoses. Generic predispositions include: central venous cannulation, recent cavity surgery, neutropenia greater than 10 days, steroids greater than 7 days, immunosuppressive therapies or diseases, ICU stay greater than 7 days, total parenteral nutrition (TPN), malnutrition, organ transplantation and burns.

Anti-fungal prophylactic therapy has become the norm in certain high-risk patient groups (e.g. haematopoietic stem-cell transplant patients [HSCT]). This has shifted the characteristic fungal infections seen, with increases in previously rare, highly resistant IFI by *Candida parapsilosis* , zygomycoses[14] and fusarium.[15]

Rarely, opportunistic mycoses develop in immunocompetent patients. Diagnosing IFI with certainty requires the isolation of fungal material from a normally sterile site. While positive identification on culture or microscopy may be diagnostic, negative microscopy and cultures cannot exclude IFI. Up to 50% of blood cultures are negative in patients with proven, disseminated IFI and/or deep-seated infection. More usually, diagnostic probability is achieved through the amalgamation of recognised risk factors, clinical picture, serological, microbiological, radiological and DNA-amplification techniques. Sequential rather than isolated data points are more informative in both diagnostic and treatment response assessments.

Aspergillosis

Aspergillosis is caused by the ubiquitous *Aspergillus* genus of moulds. In humans, *A. fumigatus* , *flavus* and *niger* are frequent invasive species. In addition, *A. clavatus* is a significant cause of allergic respiratory disease.

Invasive aspergillosis is usually evidenced in immunocompromised patients. However, it also occurs in apparently immunocompetent patients with:

- intercurrent illnesses, such as pancreatitis, liver disease, diabetes, COVID-19, influenza
- chronic lung disease, especially when on regular low-dose steroids
- exposure to high spore loads.

Entry is via inhalation of spores into the lungs or sinuses and symptoms are non-specific: dyspnoea, cough, fever, haemoptysis, malaise and discomfort in the chest. Resting hypoxaemia is common at presentation. Pneumothorax is a rare complication.

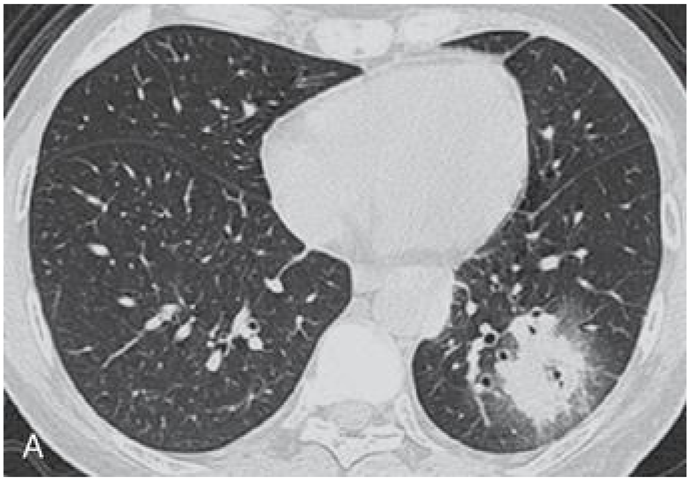
Pulmonary aspergillosis describes a spectrum of disorders from localised simple aspergilloma (this may still result in haemorrhage or bronchopleural fistula by tissue erosion) through allergic bronchopulmonary aspergillosis, to progressive multisite pulmonary disease with extensive, cavitating, tissue destruction. Invasive disease may lead to systemic infection of the brain and solid organs.

Even with appropriate surgical and amphotericin therapies, mortality of invasive aspergillosis ranges from 88% in disseminated disease to 24% in localised sinus or pulmonary disease.[16] HSCT patients (especially from matched unrelated donors) have poorer outcomes although mortality has fallen from greater than 95% in the 1990s to 80%–90% since 2002.[17]

Diagnosis

- Positive cultures or microscopic identification from samples provides the greatest certainty.
- Focal lesions may be found on chest, liver or brain computed tomography (CT) or magnetic resonance imaging (MRI) scans with or without the characteristic halo sign (Fig. 19.2A). Changes may be subtle and easily overlooked even in established diseases.

- Positive PCR of body or bronchoalveolar lavage (BAL) fluids facilitates faster diagnosis than cultures and microscopy; sensitivities and specificities up to 90% are reported.
- Galactomannan identification in BAL-fluid, urine, serum or cerebrospinal fluid (CSF) is relatively specific for *Aspergillus* although cross-reactivity can occur with Penicillium species. Beta-lactam antibiotics and dietary ingestion of galactomannan (dairy and cereal products) can also cause false positives. Sensitivities of 80% have been achieved in patients not receiving prophylactic therapy. Prophylactic therapy may reduce fungal load, and sensitivity is reported to fall to around 20%.
- β-D-Glucan detection in BAL-fluid or serum is useful but shows cross-reactivity with other fungal pathogens (e.g. *Candida*) and false positives with beta-lactam antibiotics, albumin and immunoglobulin administration and during renal replacement therapies using cellulose membranes.
- The combination of positive galactomannan and β-D-glucan tests may improve specificity reducing the likelihood of a false-positive result. [18]



The four-part radiological panels are labelled A, B, and C. Part A, in the top left, is a transverse computed tomography section of the chest showing lung fields with multiple radiodense markings and a prominent lesion in the lower right lung region adjacent to the pleura. The heart and surrounding vascular structures are visible in the centre. Part B, in the top right, is a transverse abdominal scan showing the liver, spleen, and surrounding structures with multiple irregular densities distributed throughout the hepatic region. Part C, in the lower left, is an axial magnetic resonance scan of the brain with contrast, showing bilateral cerebral hemispheres and ventricles, with ring-enhancing lesions located near the basal ganglia. The last unnumbered panel in the lower right is an axial magnetic resonance scan without contrast, showing the same anatomical plane with hyperintense signal changes around the basal ganglia and periventricular regions. The sequence of scans presents cross-sectional views of different body regions exhibiting structural variations and focal abnormalities.

imaging (MRI) of patient with cryptococcal leptomeningeal disease showing low signal in T1-weighted and high signal in T2-weighted scans. (*Case reproduced courtesy Dr Mauricio Macagnan* , Radiopaedia.org , *rID: 53172* .)

Treatment

First-line therapy for invasive aspergillosis is usually with systemic voriconazole. [19] Liposomal amphotericin B and isavuconazole are alternatives. [20] Echinocandins should not be used as first-line agents. Combination therapies with echinocandins and azoles or amphotericin have been described; some small studies suggest superiority to single-agent regimens. [21] The outcomes of larger studies are awaited, and routine combination therapy remains unusual.

Treatment duration is determined by clinical and radiological response rather than serological marker determination. Conversion to oral therapy with voriconazole or itraconazole may be considered once significant improvement is secured.

Resection of pulmonary lesions, pulmonary-vascular therapeutic embolisation for pulmonary haemorrhage, granulocyte transfusions [22] and the use of interferon-gamma [7] anti-fungal agent combination therapy (in refractory disease) are described in the medical literature.

Candidiasis

Candidiasis remains the most common IFI diagnosed globally, accounting for greater than 60% of ICU IFIs. Mortality exceeding 50% is common. Late diagnosis and suboptimal treatment lead to poorer outcomes.

Candida albicans' predominance has been superseded by *tropicalis* , *glabrata* , *parapsilosis* and *krusei* in some locations, particularly following prophylactic therapy with fluconazole. Where broader spectrum prophylactic agents (voriconazole and posaconazole) are used, the overall incidence of opportunistic candidiasis is falling but infections with resistant fungi (e.g. zygomycoses and fusarium) are rising.

Early symptoms of invasive candidiasis are non-specific; fever, chills, malaise and dyspnoea. Sites of secondary infection may offer more localised signs and symptoms (e.g. joint pain, visual impairment with loss of red reflex on ophthalmoscopy and neurological disturbances).

Diagnosis

- Greatest certainty requires positive cultures or microscopic identification in samples from normally sterile sites.
- Focal lesions may be found on chest, liver or brain CT or MRI scans (see Fig. 19.2B) but frequently lag behind serological testing for fungal DNA or cell wall components. During neutropenia, radiological appearances of abscess can almost entirely disappear from CT with reappearance when counts recover, misleading the unwary. [23]
- T2-Candida panel – FDA-approved assay for candidaemia in whole blood using PCR and amplicon-induced agglomeration of T2-MRI detected particles. Early studies indicate high negative predictive value and sensitivity for the five commonest *Candida* species with results available within 5 hours.
- Specific fungal PCR may offer sensitivities and specificities of greater than 90%. These are not yet widely available.
- Mannan antigen/anti-mannan antibodies, when measured concurrently, may offer sensitivity and specificity of testing of above 80%. [24]
- β-D-Glucan detection in BAL-fluid or serum with the same caveats as outlined for use in *Aspergillus* diagnosis.
- Scoring systems (Table 19.3), such as Paphitou's, Ostrosky-Zeichner's and Nebraska Clinic's, all offer high (>95%) negative predictive values but low positive predictive values (<50%).
- Limited-availability PCR, nanoparticle hybridisation techniques are being developed and reportedly show excellent sensitivity and specificity.
- Enzyme-linked immunosorbent assay (ELISA) for serum enolase, an enzyme secreted by many *Candida* species, and immunoglobulin G (IgG) to enolase are being investigated but are not yet widely available.

- Detection of D-arabinitol, a metabolite of some *Candida* species, in serum or BAL-fluid, appears to predict invasive candidiasis ahead of culture positivity. It remains under investigation.

Treatment

Pharmacological treatment of candidiasis varies with species and should be guided by local sensitivity patterns. A typical sensitivity chart is offered (

Table 19.4). Combination therapy with flucytosine has evidence of improved efficacy when CNS involvement or endophthalmitis is present. Some experts also recommend this when treating *Candida* endocarditis.[25], [26] Regular therapeutic drug monitoring is required; peak flucytosine levels should be maintained below 100 mg/L to avoid toxicity (target 2-h post-dose peak = 70–80 mg/L).

Cryptococcosis

Cryptococcosis – *C. neoformans* , an encapsulated yeast found in soil and bird excrement, enters the body via inhalation. Initial infection may be asymptomatic or cause non-specific inflammatory symptoms of fever, cough and dyspnoea. In immunocompromised hosts (especially HIV, organ transplants or concomitant cytomegalovirus (CMV) infection), it spreads haematogenously, causing disseminated disease commonly including the CNS, where it classically results in meningoencephalitis, hydrocephalus, seizures, a reduced Glasgow Coma Scale and neurological deficits. Permanent cranial nerve palsies and visual and hearing impairment are common.

Cryptococcus can exert immunomodulatory effects, including inhibition of phagocytosis and stimulation of peripheral blood monocyte interleukin-10 secretion with consequent pro-inflammatory cytokine production suppression. [27] Following eradication of Cryptococcus from the CNS, paradoxical inflammation may occur [28] as the immunosuppressive, anti-inflammatory effects of the pathogen diminish; Cryptococcus-immune reconstitution syndrome (c-IRS). A similar syndrome occurs when highly active anti-retroviral therapy (HAART) is commenced too soon after anti-fungal therapy in Cryptococcus presenting as AIDS, and immunity is restored before fungal load in the CNS reduces sufficiently. [29]

C. gattii is also an encapsulated yeast found in soil, trees and animal faeces. Previously largely confined to northern Australia and Papua New Guinea, more recently it emerged in America and India. Unlike *C. neoformans* , *C. gattii* , readily invades immunocompetent hosts and can multiply within white blood cells. CNS infection is common and rapidly progressive. Even previously healthy individuals show high fatality rates.

Diagnosis

A high index of suspicion is required to facilitate early diagnosis and treatment of cryptococcosis. Diagnosis typically occurs earlier in HIV or post-transplantation patients than in other groups owing to the well-recognised association. This may be the cause of better outcomes for cryptococcosis in HIV patients compared with other groups.

Diagnostic steps include:

- Positive serum cryptococcal antigen.
- MRI scanning may demonstrate dilated perivascular spaces and basal ganglia pseudocysts. Cryptococcomas demonstrate a high signal in T2/flair (see Fig. 19.2C) and a low signal in T1 (without gadolinium). CT brain scans cannot exclude diagnosis: 40% are normal, 40% reveal non-specific abnormalities and 10%–20% offer suggestive features such as abnormal masses and hydrocephalus.
- Tissue biopsy and microscopy with India Ink, Alcian Blue or Fontana-Masson staining.

- CSF sampling, microscopy, biochemistry, cytology and testing for cryptococcal antigen.
- CSF cultures for at least 5 days on Saboraud Agar if CSF analysis reveals increased leucocytes or low glucose.

Treatment

In severe cryptococcal or CSF antigen-positive infection, prolonged, high-dose, intravenous (IV), anti-fungal therapy is indicated.

- Efficacy is best proven for liposomal amphotericin B in combination with IV flucytosine therapy.
- Fluconazole 400 mg/day may be required for 1–2 years in those with residual irresectable cryptococcomas. Posaconazole crosses the blood–brain barrier well and has been shown to be efficacious against cryptococcal CNS infection in small case series – divided doses totalling 800 mg/day are recommended. Itraconazole does not cross the blood–brain barrier and should be avoided.
- Management of raised intracranial pressure (ICP) using shunts or drains is required if obstructive hydrocephalus develops.
- Dexamethasone may offer benefits to some patients with persistent neurological abnormalities despite normal ICP and culture-negative CSF following successful anti-fungal therapy for *C. gattii* [30] and in the treatment of confirmed immune reconstitution syndrome (IRS) following anti-retroviral therapy (ART) in AIDS; however, routine co-prescription with anti-cryptococcal therapy worsens outcomes. [31]
- c-IRS may benefit from corticosteroids, thalidomide or other immunomodulators. [32]

In disseminated disease without CNS involvement, fluconazole, itraconazole or posaconazole may be used. Treatment should continue from 6 to 24 months depending upon the immunocompetence of the patient.

Penicilliosis

Most commonly found in patients with HIV and CD4 counts less than 100/mm^3, who have lived or travelled in China and Southeast Asia, penicilliosis is caused by inhalation of spores of the dimorphic fungus *Penicillium marneffei*. Presentation usually occurs at the stage of disseminated rather than pulmonary infection with fever, weight loss, dyspnoea, cough, anaemia, lymphadenopathy and hepatomegaly. Papular and follicular skin and oropharyngeal lesions (see Fig. 19.1C), sometimes with central necrosis, are common.

Diagnosis is by microscopy and culture of biopsied lesions. With prompt treatment, mortality falls to around 20%. Amphotericin B enjoys the greatest success in case series to date. Two weeks of IV amphotericin followed by 6 weeks of IV itraconazole and then ongoing maintenance prophylactic oral itraconazole is recommended.

Pneumocystosis

Pneumocystis jirovecii pneumonia (PJP) was once considered a protozoan rather than a fungal infection. Gene sequencing resulted in its reclassification. It differs from most fungi by the substitution of cholesterol for ergosterol in its cell wall; this may explain the rarity of extrapulmonary invasion. This substitution renders the standard anti-fungal polyenes (amphotericin B) and azoles impotent. In animal models, echinocandins slowed or even halted disease progression, but cessation of therapy was associated with immediate relapse.

IgE and IgG measurement indicates that asymptomatic childhood PJP infections are common. Symptomatic pathology normally requires impaired host immunity, especially that associated with CD4 cell counts less than 200/mm^3 in HIV. Non–HIV-related PJP infections are usually associated with immunosuppression secondary to haematological malignancy or immunosuppressive therapies used in transplant, cancer or rheumatological disease management. Previous or current CMV infection also predisposes to PJP infection through reduced helper T-cell function. PJP infections are often more severe and diagnosed later in the non-HIV patient population. This is likely related to the widespread use of prophylactic therapy and a higher awareness of PJP amongst HIV-positive patients.

Early symptoms of PJP are often non-specific. They include malaise, dyspnoea and a non-productive cough. As infection progresses, pyrexia, weight loss, worsening cough, dyspnoea and exertion-induced hypoxia are characteristic. Pneumothorax arises in a minority of patients. Although CXR appearances are classically of widespread infiltration arising from the hila, occasionally more localised, infiltrative patterns and cavitating lesions are seen. CXR may appear normal in up to 40% of patients at presentation, whereas high-resolution computed tomography (HRCT) usually demonstrates ground-glass opacification.

Diagnosis

Clinically, suspicion of PJP on the basis of history, characteristic radiological findings and a known predisposition is sufficient justification to initiate treatment before laboratory confirmation. Delays in starting therapy, even by one day, are associated with significant increases in mortality.

Confirmation or exclusion of the diagnosis is achieved by:

- demonstration of PJP using immunofluorescence or silver staining of induced sputum or BAL samples
- demonstration of PJP DNA on PCR of BAL and/or peripheral serum samples.

Treatment

Co-trimoxazole inhibits folic acid synthesis in *P. jirovecii* via two separate pathways. It is the agent of first choice. Administered intravenously in high doses (120 mg/kg per day in divided doses) for 21 days, drug intolerance results in around 50% of patients requiring a change of agent. Co-administration of IV steroids has been shown to reduce mortality in HIV patients. Their use is recommended in severe disease where the alveolar-arterial oxygen gradient is greater than 35 mmHg (4.6 kPa) or $PaO_2 < 70$ mmHg (9.3 kPa) and may reduce the inflammatory response and worsening respiratory failure associated with treatment-induced fungal lysis. Dose regimens in the range of 1–2 mg/kg methylprednisolone for the first 10 days of anti-fungal therapy are described. [33] Steroid treatment at lower dose rates may be continued while IV cotrimoxazole is ongoing, but this is not universal.

Alternative therapeutic regimens for those intolerant of cotrimoxazole include:

- pentamidine IV 4 mg/kg o.d. (1× daily), or
- clindamycin 450 mg q.i.d. (4× daily) and primaquine 30 mg o.d., or
- dapsone 100 mg o.d. and trimethoprim 5 mg/kg q.i.d. and
- atovaquone 750 mg b.d. (2× daily).

In addition, combination therapy with clindamycin and caspofungin has been described as providing successful treatment of severe PJP in isolated case reports. [34]

Zygomycoses

Zygomycoses [35] consists of two orders of fungi: Mucorales and Entomophthorales. Sometimes the former term is used interchangeably with mucormycosis as the majority of infections seen are secondary to Mucorales, a ubiquitous, angioinvasive mould that causes tissue necrosis and characteristic cutaneous, sinus, cerebral, pulmonary, gastrointestinal and disseminated infections. The main species causing human infection are *M. Rhizopus* , *M. Lichtheimia* and *M. Mucor* . Fungal spores may be inhaled, ingested or cause direct infection via damaged membranes.

Disseminated disease is usually fatal in immunocompromised hosts. Mucormycosis is the third commonest invasive fungal disease (IFD) in patients receiving haematopoietic stem-cell transplants, causing 1%–2% of IFI in this group. The incidence is rising secondary to the widespread use of broad-spectrum, prophylactic anti-fungal agents such as voriconazole in a bid to reduce *Aspergillus* and *Candida* infections. [36] In addition, infections are associated with poorly controlled diabetes, haematological malignancy (especially acute myeloid leukaemia [AML]), trauma, iron overload, acidosis (especially ketoacidosis), malnutrition and steroids. All of these risk factors appear amplified by intercurrent COVID-19 infection:

- poor diabetic control is associated with rhino-ocular cerebral mucormycosis
- malignancy with disseminated mucormycosis
- and severe COVID-19 itself with pulmonary mucormycosis.

Even with combined surgical and polyene therapy, mortality of mucormycosis reaches 80% in ICU-admitted patients.

Initial symptoms are seldom specific, reflecting mild inflammation at the site of inoculation. After a period of malaise, fever (50% of patients) and symptoms of site-specific local inflammation (e.g. sinusitis), evidence of invasion may develop with progression of cough and dyspnoea to haemoptysis or sinusitis to cellulitis of the skin over the paranasal sinuses. Unmanaged, further invasion will lead to pulmonary haemorrhage, bronchial occlusion and mediastinitis in pulmonary cases and orbital, ocular and cerebral invasion, cranial nerve palsies and skin necrosis in sinus ones. Where skin invasion occurs, a black eschar is often seen.

Diagnosis

Early diagnosis and treatment of mucormycosis before angioinvasion and dissemination are essential to improve survival. Diagnostic steps include:

- a high degree of suspicion based on clinical risk profile
- early recognition of characteristic skin lesions
- CT findings (e.g. nodules, halo signs, reverse halo signs and wedge infiltrates on lung CT), and MRI findings with low intensity on T1 and high intensity on T2 with leptomeningeal disease
- microscopy of samples from sinus drainage, abscess drainage, BAL or tissue biopsy using wet mount slides with calcofluor staining and periodic acid-Schiff (PAS) or Grocott's methenamine silver (GMS) dry-mount staining
- culture – usually positive in 3–5 days unless receiving appropriate anti-fungal therapy at the time of sample collection
- PCR and molecular diagnostic techniques are currently in evolution but are not yet widely commercially available.

Treatment

Amphotericin B (preferably as a lipid formulation) is the mainstay of treatment with proven efficacy in vitro and in vivo. A dose of 5 mg/kg lipid formulation per day has been suggested. Retrospective human studies and prospective animal studies suggest improved survival [14] utilising combination therapy of a lipid-formulated polyene and an echinocandin. [37] Azoles are not recommended in the treatment of human mucormycosis, although very high-dose posaconazole has seen some success in animals. Survival may be associated with life-changing disability; pooled data reported 46% of COVID-associated rhino-sinus cerebral mucormycosis survivors had loss of vision.

Entomophthorales infection is usually restricted to skin and subcutaneous infections in tropical areas and largely occurs as a primary rather than opportunistic infection. It is not normally angioinvasive and disseminated disease is largely confined to immunocompromised individuals.

Others

A large and growing variety of opportunistic fungal infections is increasingly recognised and it is beyond the scope of this chapter to cover all of those that may be encountered. In addition to the commonest infections outlined above, the possibilities of rarer infections with fusariosis, hyalophomycoses, phaeohyphomycoses and scedosporium merit consideration in immune-compromised patients with infection of unknown aetiology, especially haematopoietic transplant recipients. [38]

Conclusion and general considerations

The definitive diagnosis of IFI is one of the great challenges of modern medicine. Identification of fungi from normally sterile sites allows definitive diagnosis, but some species take weeks to grow and tissue samples are rarely obtained early during a patient's stay. Additionally, certain fungi require specific, non-routine staining for identification. Antibody/antigen testing of fungal components and PCRs of fungal DNA are improving rapidly and certainty of diagnosis for certain species, but are far from perfect across the range of pathogenic fungi. T2-Candida MRI shows promise in rapid identification of *Candida* species from blood samples.

In 2020, a revised consensus definition of IFD was published by the European Organisation for Research and Treatment of Cancer/IFI Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group. [39] This classified secondary IFI as definite, probable or possible. The consensus definitions' utility lies in categorising patient groups during research and epidemiological studies, facilitating comparisons between different studies using a common definition. They should not be used to determine a tipping point as to whether to treat a patient for 'probable' IFI or not and are deliberately omitted here. A retrospective re-analysis of neutropenic patients treated for IFI based on the 2002 criteria demonstrated a significant shift of treated patients from 'probable' (2002) to 'possible' (2008), and increased survival in the group now re-classified as 'possible'. As all had received treatment, the authors suggested this may indicate that treatment earlier in the course of infection, before diagnostic certainty increased, resulted in better outcomes. [40]

Until the advent and widespread availability of high sensitivity and specificity test(s) covering the spectrum of recognised fungal infections seen in the ICU, high awareness of the possibility of primary and secondary mycoses, an understanding of the available diagnostic tests and algorithms together with knowledge of their limitations, offers the best chances of early diagnosis and the instigation of appropriate treatment. Even with appropriate treatment, the mortality of IFD in the ICU remains over 50% for many fungi. Poorer outcomes are seen when diagnosis and treatment are delayed.

Principles of antimicrobial use in the intensive care unit

Marta Ulldemolins, Jason A. Roberts and Jeffrey Lipman

Introduction

The intensive care unit (ICU) is always the area of any hospital associated with the greatest use of antimicrobials. More than two-thirds of the patients in an ICU have been reported receiving antimicrobials at any one time. [1], [2] Therefore the majority of the patients will receive at least one antimicrobial course during their stay. Most of these prescriptions are unavoidable, as early and appropriate antimicrobial therapy is a major determinant of clinical outcomes of septic shock [3] and, if the clinical suspicion exists, they must be started without delay. However, clinicians working in an ICU must realise that there is an essential consequence of this use [4] ; antimicrobial use selects the growth of other non-susceptible organisms, especially antimicrobial-resistant bacteria and fungi, that congregate where these organisms' advantage is greatest. Adverse events, resistance and changes in patient flora are collateral damage directly related to every antimicrobial usage. [4] Therefore every course of inappropriate antimicrobials should be avoided so as to help reduce the burden of antimicrobial resistance, which has also a direct impact on ICU ecology and other patients' infections by resistant bacteria.

Antimicrobial stewardship (AMS) [5] principles include the selection of an appropriate drug and an optimised dose and duration to treat an infection. The process must include a multidisciplinary team of physicians, microbiologists, pharmacists and infection control specialists. AMS must be seen not only as an ecological tool for limiting resistance spread but also as a way to individualise antimicrobial therapy and minimise collateral damage. [4,5] For the optimal use of antimicrobials not only should antimicrobial pharmacology be understood but also there should be clear and rational principles on which each specific antimicrobial prescription in the ICU is based.

This chapter aims to provide general principles for the use of antimicrobial agents in the ICU. Although it goes through the principal characteristics of most of the antimicrobial families commonly prescribed in the ICU, it is beyond the scope to specifically address the details of every molecule class; further information should be gathered in specific texts.

General principles

- Every effort must be made to properly **diagnose and characterise** infection. Appropriate microbiological sampling, always including blood cultures, must be obtained as soon as possible and before commencing antimicrobial therapy. [6] Rapid diagnostic tools including multiplex polymerase-chain reaction (PCR) panels for different biological samples may assist with aetiological diagnosis and targeted therapy and must be considered at admission if serious infections such as meningoencephalitis or severe community-acquired pneumonia are suspected. [7,8]
- **Blood cultures** must be taken from a venipuncture site, after adequate skin antisepsis. Two separate sets of 20–30 mL (for adults, aerobic and anaerobic) should be collected. [9] If catheter-related sepsis is suspected, one of the sets must be extracted from the catheter simultaneously as the peripheral set for evaluating differential time to positivity (≥2 h highly suggestive). [10]
- Once a presumptive diagnosis of severe infection/septic shock and a decision to administer antimicrobials are made, they should be **administered without delay** , as delays to antimicrobial therapy

(even delayed correct therapy) in this context are associated with higher mortality and morbidity. [3, 11]

- Inappropriate antimicrobial prescription in severe infections has also been shown to result in poorer outcomes. [12] Therefore appropriate therapy usually requires starting off with **empirical broad-spectrum antimicrobials, even a combination** , [11] for covering for the most likely pathogens (Table 20.1). An immediate Gram-stained report may guide (with limitations) an empirical antimicrobial choice, otherwise an **informed 'best guess' decision** has to be made depending on the clinical situation. This should take into account various factors such as common pathogens associated with each source of infection, community- versus hospital-associated infections, history of immunosuppression, recent antimicrobial prescription, ward- versus ICU-acquired infection, travel history, known or probable colonisation by resistant organisms and knowledge of local epidemiology. These latter points are where ward/unit surveillance becomes important. [13–15]
- When microbiological results are available, **early therapy de-escalation** must be instituted. De-escalation consists of simplifying the components of an antimicrobial combination and narrowing the antimicrobial spectrum to target the isolated microorganism. It is recommended to be performed within 24 h of definitive culture results and antibiogram availability, and it is a strategy to minimise the overall exposure to broad-spectrum agents for decreasing the ecological impact (Table 20.1). [16, 17] The benefits of de-escalation are difficult to quantify in clinical studies due to the high heterogenicity of the population of critically ill patients with severe infections, but they include a potential reduction in antimicrobial resistance without a negative impact on survival and length of stay. [17]
- **Empirical antifungal therapy** in sepsis should be considered in patients with risk of disseminated candidiasis, that is, patients with complicated abdominal sepsis, those receiving parenteral nutrition, neutropenic or immunosuppressed patients, intravenous drug users

or those patients with risk factors in refractory shock despite broad-spectrum antimicrobials and an adequate source control. In these cases, depending on local epidemiology, an echinocandin or lipidic amphotericin B may be considered as empirical therapy until culture results.[11, 18] If invasive *Aspergillus sp* infection is suspected in a susceptible host (especially neutropenic/severely immunosuppressed, even under prophylaxis), early and adequate diagnostic tests should be performed, including high-resolution imaging, cultures, pathology, molecular and biomarkers determination (e.g. galactomannan antigen detection and *Aspergillus sp* specific PCR assay) in bronchoalveolar fluid and blood.[19] Different approaches have been designed (empirical, pre-emptive and targeted)[19] for the decision of specific therapy initiation depending on the particular situation of the patient; joint evaluation with an infectious diseases specialist is mandatory in this scenario.[19]

- **Empirical antiviral therapy** with high doses of acyclovir (10 mg/kg/8h) should be considered in patients with suspicion of viral herpesvirus meningoencephalitis until the diagnostic test results are available.[6] When cytomegalovirus reactivation is suspected in a compatible host (mainly severely immunosuppressed), plasma quantification of viral load is recommended before starting antiviral therapy due to the high toxicity of the available antivirals. Other diagnostic tests may be required to confirm diagnosis of organ-specific cytomegalovirus infections, that can happen even with low plasma viral loads.[6, 20, 21]
- **Combination targeted antimicrobial therapy** may be advantageous in some selected scenarios, while harmful in many others. For example when a dual mechanism of action is required, e.g. an antitoxin effect in exotoxin-mediated necrotising infections like streptococcal fasciitis, combination therapy with a β-lactam and an anti-toxin antimicrobial (such as clindamycin or linezolid) is associated with better clinical outcomes.[22, 23] Further, combination therapy may be considered for high inoculum infections and/or those caused by less susceptible strains (including

multidrug resistant) of *Pseudomonas aeruginosa* , also with the aim of preventing the emergence of resistance, [24] even though the available clinical evidence is not conclusive. [25–27] If combination therapy is desired, agents with different mechanisms of action would be preferable.

- Positive cultures from clinical samples (particularly non-blood/sterile site culture isolates) do not always mean infection, and in general antimicrobial therapy should not be initiated without a clinical suspicion of infection. **Distinguishing colonisation versus infection** can be challenging with positive microbiology results only (endotracheal aspirates in patients on mechanical ventilation), and the diagnosis must be informed by an exhaustive physical examination and a correct interpretation of the complementary tests including cultures (sterile vs. non-sterile sites, possibility of contamination or colonisation). [6] Knowledge about the microbiology of different infectious syndromes is paramount (e.g. *Candida sp* pneumonia is highly unlikely, even if there is growth of *Candida sp* in low respiratory tract samples). [28]
- Lack of clinical improvement and persistent inflammatory response must be carefully evaluated before ‘blaming’ the antimicrobial, especially when cultures are available and the treatment is theoretically targeted. [6] Other causes of suboptimal response, mainly inadequate **source control,** [29] must be considered and addressed before starting ‘antimicrobial surfing’ (i.e. switching from one combination to another).
- General signs of infection are very similar to signs of systemic inflammation. Although bacterial infection is likely in the ICU environment, **non-bacterial infection and non-infective causes of inflammation/fever/shock** should also be considered and carefully evaluated in the differential diagnosis. [6] High procalcitonin and C-reactive protein concentrations may be helpful for infection but are often too non-specific and have significant limitations. [30], [31]
- **Duration** of antimicrobial treatment must be tailored to each particular infection, paying special attention to source control; a standard 2-week course of antimicrobials is unnecessary in the

majority of the cases[32–34] and probably harmful (Table 20.1). The overgrowth of resistant organisms, a ‘natural’ consequence of broad-spectrum antimicrobial use, is termed ‘collateral damage’; after a single day of imipenem, some patients will grow imipenem-resistant bacteria in their faeces.[35] It is nowadays broadly accepted that with adequate source control, even abdominal sepsis can be treated with a short course of antimicrobials.[11, 32] At the bedside, favourable clinical evolution and progressive decrease of acute-phase biomarkers such as C-reactive protein and procalcitonin suggest resolution of infection and might assist physicians in making individualised antibiotic therapy decisions, including early discontinuation.[31, 36] However, important exceptions apply here, such as infective endocarditis, deep-site infections or infections with sub-optimal source control, where longer antimicrobial courses are necessary.

- **Multidisciplinary clinical teams,** including intensivists, infectious diseases/clinical microbiology specialists and clinical pharmacists are always useful and should be considered mandatory for the care of patients with serious infections.[6] Additional tests, such as minimum inhibitory concentration (MIC), antimicrobial assays, serum bactericidal activity and synergy tests of antimicrobial combinations may be useful in serious infections (e.g. endocarditis, multidrug resistance and infections in immunocompromised patients). Susceptibility tests should be interpreted carefully. *In vitro* susceptibility does not equate with clinical effectiveness; *in vitro* resistance is probably more helpful for the clinician but expert opinion must be sought.
- The **pharmacokinetics and pharmacodynamics** as well as the spectrum of activity of the antimicrobial must be considered. Antimicrobial pharmacokinetic principles should determine the dosage and frequency of antimicrobial regimens.[37, 38]
- **Adequate drug doses** should be given. Under-dosing leads to overgrowth of resistant organisms (Table 20.1).[39] The intravenous route is preferable in critically ill patients, but complementary routes should be considered when appropriate (e.g.

combination with nebulised colistin for ventilator-associated pneumonia caused by multi-resistant Gram-negative bacilli).[40], [41]

- **Therapeutic drug monitoring (TDM) of antimicrobial plasma concentrations** (and dose titration accordingly) is helpful not only for avoiding toxicity but also for increasing efficacy (prevention of underdosing), which is endorsed by most of the scientific societies and should be performed where possible.[42] Compelling data suggest that many patients are underdosed in ICUs, especially those affected by augmented renal clearance (CL).[43], [44]
- **Prophylactic use of antimicrobials** should be limited to certain situations, should cover organisms that potentially can cause infections in that specific group of patients and should be given at the appropriate timing.[45]

Table 20.1

Contemporary paradigm of treatment for healthcare-associated sepsis

OLD PARADIGM	NEW PARADIGM
Start with narrow spectrum	Ensure appropriate therapy with a broad spectrum and then de-escalate
Cost-efficient low dose	Aggressive dosing upfront
Low doses → fewer side effects	Low doses → subtherapeutic concentrations and resistance
Prolonged antimicrobial courses ≥2 weeks	As short as possible antimicrobial courses (<7 days)

Modified from Lipman J, Boots R. A new paradigm for treating infections: "go hard and go home". *Crit Care Resusc* . 2009;11(4):276–281.

Specific issues

1. Antimicrobial physicochemistry and pharmacokinetics in the critically ill patient

Physicochemical characteristics of antimicrobials can help predict their pharmacokinetic behaviour. Hydrophilic drugs distribute into intravascular and interstitial spaces but are unable to cross the lipid cellular membrane and, therefore, do not distribute intracellularly. Their volume of distribution (Vd) is then similar to extracellular (intravascular and interstitial) water and usually corresponds to a value between 0.1 and 0.3 L/kg. [37] They normally do not undergo hepatic metabolism (as they are hydro-soluble by definition) and their clearance (CL) is usually dependent on renal function. Lipophilic drugs can cross lipid membranes and therefore are more likely to distribute into the cells and to the lipid-containing tissues, such as adipose tissue and central nervous system. Plasma concentrations, consequently, are lower than observed with hydrophilic drugs, and their Vd is larger than total body water. Table 20.2 classifies the different antimicrobial families by their hydro/lipophilicity.

Table 20.2

Classification of the main antimicrobial families by water solubility

Hydrophilic	Lipophilic
β-lactams	Quinolones
Carbapenems	Macrolides
Glycopeptides	Rifampicin and rifamycins
Aminoglycosides	Lincosamides
Daptomycin	Metronidazole
Linezolid	Tetracyclines and tigecycline
Azoles (fluconazole)	Azoles (fluconazole, voriconazole, posaconazole, isavuconazole)
Echinocandins (caspofungin, micafungin)	Aciclovir
Ganciclovir	Amphotericin B (deoxycholate and liposomal formulations)
Foscarnet	Echinocandins (anidulafungin)

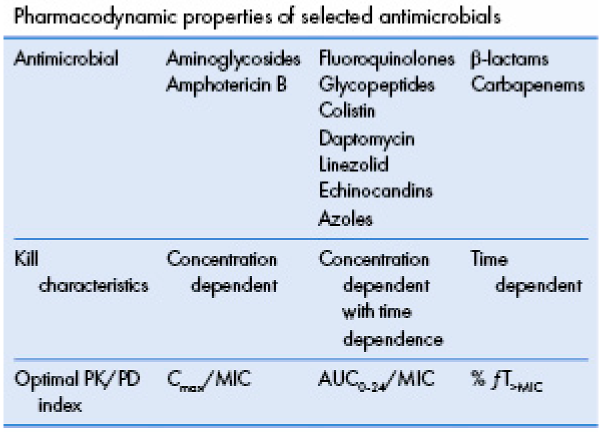
From Roberts JA, Lipman J. Pharmacokinetic issues for antibiotics in the critically ill patient. *Crit Care Med* . 2009;37(3):840–851. doi: 10.1097/CCM.0b013e3181961bff .

In the context of critical illness and sepsis, these pharmacokinetic characteristics are subject to change due to the disease itself and the clinical management thereof, especially for water-soluble drugs. Increased Vd for hydrophilic drugs should be expected as a consequence of systemic inflammation, hypoalbuminemia, capillary leakage and fluid resuscitation measures.[37] Changes in renal elimination, for renally cleared drugs, should be anticipated as well. On one hand, augmented renal CL secondary to a hyperdynamic state is a condition increasingly documented as a ‘silent’ cause of underdosing[44] ; on the other hand, sepsis-related acute kidney injury can lead to supratherapeutic concentrations and toxicity.[37] Hepatic impairment and extracorporeal therapies like renal replacement therapy, extracorporeal membrane oxygenation or plasmapheresis must be taken into account as well as other causes of different dosing requirements.

2. Antimicrobial pharmacodynamics and dosing principles

The various antimicrobial classes have different ‘kill characteristics’, that is, pharmacodynamics, and therefore should be dosed differently to achieve concentration-time profiles associated with maximal effects (Table 20.3).[37], [38], [46] The following is a (non-extensive) overview of the pharmacodynamics of the main antimicrobial classes, with general dosing recommendations and some relevant particularities to be considered in daily clinical practice.

Table 20.3



Pharmacodynamic properties of selected antimicrobials

Antimicrobial	Aminoglycosides Amphotericin B	Fluoroquinolones Glycopeptides Colistin Daptomycin Linezolid Echinocandins Azoles	β-lactams Carbapenems
Kill characteristics	Concentration dependent	Concentration dependent with time dependence	Time dependent
Optimal PK/PD index	C_{max}/MIC	AUC_{0-24}/MIC	% $fT_{>MIC}$

AUC_{0-24} , Area under concentration time curve during a 24h period; C_{max} , peak serum concentration; % $f\,T_{>MIC}$, percentage of time while unbound concentration is maintained above the MIC; *MIC* , minimum inhibitory concentration; *PD* , pharmacodynamic; *PK* , pharmacokinetic.

From Roberts JA, Lipman J. Pharmacokinetic issues for antibiotics in the critically ill patient. *Crit Care Med* . 2009;37(3):840–851. doi: 10.1097/CCM.0b013e3181961bff .

β-Lactams (Penicillins, Cephalosporins, Monobactams and Carbapenems) [37, 38, 46]

1. *In vitro* studies of β-lactam antimicrobials on Gram-negative bacilli show a bactericidal activity that is almost entirely related to the time that free (i.e. active) antimicrobial concentrations exceed the MIC of the bacteria for a certain threshold ($fT_{>MIC}$). These studies suggest that the minimum time that plasma β-lactam unbound concentrations should exceed the MIC is around 50% of the dosing interval ($50\%fT_{>MIC}$), although is different for the different β-lactam classes. [46]

2. The post-antimicrobial effect (PAE) is the continued suppression of bacterial growth despite no measurable serum concentration of the antimicrobial and depends on several factors, including the antibiotic class and the magnitude of the peak concentration. With the exception of carbapenems, that have some PAE, β-lactams lack a significant PAE, particularly against Gram-negative organisms, for which it is not necessary to achieve very high peak plasma concentrations.[37,39,46] It is suggested that when β-lactam concentrations exceed four to five times the MIC for long periods, maximum killing of bacteria *in vitro* occurs.[37,39,46] Conversely, *in vitro* data suggest that low concentrations may predispose to the development of resistant organisms and that more aggressive targets up to 100%$fT_{>MIC}$ or even higher, 4 × 100% $fT_{>MIC}$, may have microbiological advantages to avoid selection/induction of resistance (especially in high inoculum scenarios).[39]
3. Thus it is important for the efficacy of β-lactams that the dosing regimen maintains adequate plasma concentrations for as long as possible throughout the dosing interval. Consequently, prolonged and even continuous infusions of β-lactams have been utilised to increase the $fT_{>MIC}$ and, conceptually, optimise bacterial killing and minimise the emergence of bacterial resistance.

   In this context, international guidelines advocate for prolonged infusions of β-lactams, recommending them over conventional bolus administration in patients with sepsis/septic shock based on the available evidence.[11,47–53] Recently, the results of a large international randomised clinical trial (RCT) comparing continuous infusion of piperacillin/tazobactam and meropenem versus bolus administration in patients with sepsis (BLING III study, n = 7031)[52] reported higher rates of clinical cure in the infusion arm and a concomitant systematic review and meta-analysis of 18 RCTs that compared prolonged infusions of β-lactams over bolus (n = 9108 patients with sepsis/septic shock) reported lower 90-days mortality with the use of prolonged infusions.[53]
4. Therefore when dosing β-lactams, prioritise standard doses with more frequent administration (i.e. 4-hourly versus 8-hourly, or

twice daily versus daily) and prolonged/continuous infusions (always after a full loading dose) over bolus to optimise the $fT_{>\mathrm{MIC}}$.[11, 52, 53] TDM of trough concentrations may help in the design of dosing strategies that optimise the $fT_{>\mathrm{MIC}}$, and is recommended by the major international scientific societies.[42]

Aminoglycosides [37, 46, 54]

1. The agents above contrast with the killing characteristic of the aminoglycosides, which is concentration-dependent. Experimentally, a high peak concentration of an aminoglycoside provides a better, faster killing effect on standard bacterial inocula, optimised when the PK/PD index ratio peak concentration/MIC ($C_{\max}$/MIC) ≥ 8–10.
2. All aminoglycosides exhibit a significant PAE. The duration of this effect is variable, but the higher the previous peak the longer the PAE. This phenomenon allows drug concentration to fall significantly below the MIC of the pathogen without allowing the regrowth of bacteria.
3. These principles allow for single daily doses of aminoglycosides. Compelling evidence shows that once-daily is more efficacious with reduced toxicity, resulting in higher $C_{\max}$/MIC ratios, further prolonged PAE and reduced administration costs.[54–56]
4. Therefore it is recommended that tobramycin and gentamicin at 7 mg/kg be administered as a loading dose on the first day, followed by 5 mg/kg/24 h, and amikacin 25–30 mg/kg as a loading dose followed by 15 mg/kg/24 h.[6, 54–57] Maintenance doses should always be guided by TDM.[42]
5. With renal dysfunction, a similar loading dose should be considered but then the dosing interval should be altered according to creatinine clearance (CrCL). If ≥60 mL/min give gentamycin 5–7 mg/kg/24 h; if 59–40 mL/min, give the same dose at an interval of 36 h; 39–20 mL/min increases the dosing interval to 48 h.[57]

Quinolones [37, 46]

1. Quinolones, in contrast, have a combination of both of the above characteristics (i.e. concentration-dependent and time-dependent effects), as well as some PAE. The most accepted PK/PD index associated with efficacy is the ratio of the area under the curve over the MIC (AUC_{0-24}/MIC). Ratios of 25–30 may suffice for Gram-positive bacteria, but higher values (≥125) may be required for Gram negative.
2. Ciprofloxacin dose should be at least 400 mg/12 h (up to thrice daily, and always when treating *Pseudomonas aeruginosa*), levofloxacin 500–750 mg/24 h (up to 1000 mg/24 h in deep site infections caused by Gram-negative bacilli, especially *P. aeruginosa*) and moxifloxacin 400 mg/24 h.
3. There is general concern about the emergence of resistance to quinolones related to sub-optimal exposure from inadequately low dosing.

Glycopeptides [37, 58]

1. Vancomycin induces a PAE and a post-antimicrobial sub-MIC effect; its activity has been correlated mainly with total exposure. Current guidelines recommend to perform TDM monitoring vancomycin C_{max} and C_{min} (or steady-state concentration (C_{ss}) if continuous infusion) for attaining a PK/PD index of AUC_{0-24}/MIC = 400–600. [58]
2. Continuous infusions of vancomycin may have some advantages, especially regarding less nephrotoxicity. [58]
3. Vancomycin’s recommended dose is at least 30 mg/kg loading dose and 30–40 mg/kg/24 h (in divided doses or continuous infusion) as the maintenance dose in patients with normal renal function. [59]

Oxazolidinones [42]

Linezolid activity is concentration-dependent with time dependence, and efficacy has been correlated to an $AUC_{0\text{-}24}/MIC = 80–120$. Its pharmacokinetics can be variable in ICU patients, for which TDM is recommended. The usual dosing of linezolid is 600 mg/12 h, but higher doses may be prescribed based on the results of TDM, considering as well that a higher exposure has been associated with haematological toxicity.

Daptomycin [42]

Daptomycin activity is related to an $AUC_{0\text{-}24}/MIC$ ratio ≥ 666, which is achieved with conventional doses of 6 mg/kg/24 h for low MICs (0.1 mg/L); higher doses (10–12 mg/kg/24 h) should be considered for the treatment of bacteria with higher MICs (like *Staphylococcus aureus*). Daptomycin is inactivated by lung surfactant, and hence it is contraindicated for the treatment of respiratory infections.

Aminoglycosides and glycopeptides distribute well into fluids of the extravascular, extracellular space and less well into tissues. This has two important implications. First, these agents should not be first-line agents, or monotherapy, for solid organ infections. Second, in situations where extravascular fluid shifts are significant (e.g. in situations of ‘third-space losses’ of abdominal sepsis and in severe burns), [37] the Vd of these drugs is significantly affected. Hence for any serum concentration required a larger than usual dose may have to be administered. The large Vd of quinolones and linezolid suggests penetration is excellent into most tissues and therefore these drugs are good for solid organ infections. Similarly, β-lactams as a group all have reasonable tissue distribution, although inconsistent cerebrospinal fluid (CSF) penetration, which may be different for each particular molecule.

Antifungals

Echinocandins [60]

Echinocandin antifungals (caspofungin, anidulafungin and micafungin) are concentration-dependent drugs with some time dependence, they have post-antifungal effects and their efficacy has been associated with both C_{max}

/MIC and AUC $_{0\text{-}24}$ /MIC in *in vitro* studies; however, the clinical PK/PD indices associated with clinical efficacy are not yet well defined. [42, 60] They are administered once daily and no major adjustments depending on organ function are required. Concern has been raised about insufficient peritoneal distribution of echinocandins for preventing the development of resistance, especially in high inoculum infections such as non-controlled peritonitis, for which in this scenario alternative agents may be considered. [61]

Amphotericin B [60]

Amphotericin B exhibits non-linear pharmacokinetics, and the PK/PD index associated with efficacy is C_{max} /MIC. Lipidic formulations have improved its pharmacokinetic and toxicokinetic profile. It exhibits a prolonged post-antifungal effect (>12 h) and is usually administered once daily. Tissue penetration is excellent, central nervous system penetration is good but higher doses are sometimes used for some less susceptible fungi (10 mg/kg/24 h for normal renal function).

Azoles [60]

1. Azoles efficacy is concentration-dependent with time dependence and has been related to AUC $_{0\text{-}24}$ /MIC. For fluconazole, an AUC $_{0\text{-}24}$ /MIC ≥50–100 has been associated with therapeutic success in invasive candidiasis; recommended daily doses are 6 mg/kg/24 h for normal renal function.
2. Voriconazole is mainly used for *Aspergillus sp* infections in the immunocompromised patient. Its pharmacokinetics are very variable and depend on cytochromes CYP2C9 and 2C19 function, for which inadequate exposure is frequent and probably enhanced in critically ill patients. TDM is mandatory and target exposure is related to a C_{min} 2–6 mg/L. It is a potent CYP2C9/2C19/3A4 inhibitor, for which drug–drug interactions must always be considered.

3. Surgical prophylaxis

The main indications for prophylaxis are [6, 45]:

- when surgery involves incision through a non-sterile area.
- when an invasive procedure potentially produces a bloodstream infection in the presence of an immunocompromised patient, or when the potential bloodstream infection occurs in the presence of an abnormal heart valve or prosthetic material.

The basic principles of choice of a prophylactic regimen are [6, 45]:

1. The organisms colonising the area through which the incision is made should be covered (Gram-positives if skin is breached, Gram-negatives and anaerobes if bowel is opened). The same concept applies to catheterisation or instrumentation (Gram-negatives for bladder catheterisation, Gram-positives and anaerobes for dental procedures in ‘at risk’ patients).
2. If the prevalence of a resistant organism in a specific area is high (e.g. *Pseudomonas aeruginosa* in burns units) then those organisms should be covered in the selected prophylactic regimen. If colonisation by a resistant organism is known previous to the procedure, targeted prophylaxis should be chosen. Microbiological screening should be performed on patients ‘at risk’.

Timing and Duration of Surgical Prophylaxis

1. Optimal blood concentrations of antimicrobial(s) are needed at the time when bacteraemia is possible, for which it is recommended to administer an initial dose of the β-lactam of choice 60 min prior to incision; in the case of administering other non–β-lactam agents like vancomycin or fluoroquinolones, which need longer infusion times, administration should be initiated within 120 min before incision, with the infusion completed within 30–60 min of incision. [45]
2. Antimicrobial re-dosing must be given if the surgery is prolonged for more than 2 half-lives of the drug or if there is excessive blood

loss.[45]

3. There is rarely any extra benefit to postoperative antimicrobial prophylaxis.

4. When not to start antimicrobials

Even with compelling evidence of the impact of antimicrobial therapy on outcomes of severe infections, there are situations where antimicrobials should not be empirically started even when an infection is possible.[62] The collateral damage of antimicrobials is well known, both in the patient (toxicity, alteration of the microbiome, colonisation and/or superinfection by non-susceptible bacteria and fungi) and in the surrounding environment and other patients.[4] Hence, a careful benefit-risk balance must be assessed taking into account the risk of antimicrobial initiation delay versus its potential harm. The clinical syndrome of sepsis has a broad spectrum of manifestations and severity, and its diagnosis has been demonstrated to be variable and challenging, especially in the ICU,[63] where clinical findings and laboratory/image alterations can be also caused by a constellation of non-infectious causes. In this scenario, it is important also to consider when and if it is *safe* to wait until a suspected infection is confirmed. In situations like hemodynamic instability with a high probability of septic shock, or suspicion of life-threatening infections such as meningitis or meningococcal sepsis, there is no doubt of the urgency of early empirical antimicrobial administration.[3] In fact, administering antimicrobials within 1 h from clinical suspicion is a major recommendation of the Surviving Sepsis Campaign guidelines for patients with possible septic shock or a high likelihood of sepsis.[11] There are other scenarios where a conservative approach of *watchful waiting* where close monitoring and antimicrobial initiation once an infection is demonstrated could be considered. For instance, in the non-shocked ICU patient with suspected infection (and onset >48 h after ICU admission), delaying initiation of antimicrobial therapy until after initial investigations aimed at sepsis diagnosis and source identification are performed may be appropriate. Hranjec and colleagues performed a pre-post quasi-experimental cohort study in post-surgical ICU patients, where they compared an aggressive early empirical antimicrobial therapy for a suspected infection with a conservative directed antimicrobial therapy once the infection was microbiologically confirmed. [64] They included patients with intraabdominal, respiratory, urinary, surgical-site and bloodstream infections (catheter-related and non-catheter-related). They found survival benefits in the directed therapy, as well as a higher rate of appropriated antimicrobial therapy and lower length of ICU stay and days of antimicrobials. [64] In spite of the methodological limitations of a single-centre, quasi-experimental study, their results suggest that, in certain circumstances, a conservative approach to antimicrobial initiation may be superior to an indiscriminate empirical antimicrobial start. The Surviving Sepsis Campaign guidelines also consider this approach and, for patients with possible sepsis without shock, the recommendation is to perform a time-limited course of rapid diagnostic tests and investigations; afterwards, if infection is still suspected as the cause of the clinical syndrome, antimicrobials must be started within 3 h from the time when sepsis was first suspected. For patients with low suspicion of infection and without shock, antimicrobials should be withheld while close monitorisation is performed. [11] Until more accurate diagnostic tests for infection and sepsis are available, thorough assessment and close monitoring of the hemodynamically stable patient with low-risk potential infections may save broad-spectrum antimicrobial overexposure, reduce days of treatment and limit collateral damage. [62]

Malaria

Introduction and Epidemiology

Malaria, a parasitic disease transmitted by the bite of the female *Anopheles* mosquito, is most prevalent in the tropical regions of Africa, Asia, Oceania and South and Central America, although sporadic cases of imported malaria occur in developed nations.[1], [2]

Five distinct species of Plasmodia can cause infection in humans. *Plasmodium falciparum* is responsible for 60% of all malaria cases while the vast majority of remaining malaria infections are caused by *Plasmodium vivax*. *P. ovale*, *P. malariae* and *P. knowlesi*, collectively known as monkey malaria, account for less than 1% of malarial infections.[3]

Severe malaria, characterised by organ failure, metabolic alterations and anaemia, occurs in around 1% of *P. falciparum* infections; if untreated, this can rapidly lead to death. In hyper-endemic areas in sub-Saharan Africa, severe malaria is uncommon in adolescents and adults since frequent infection in children results in natural immunity by 6 years of age.[3] In other endemic regions of Asia, the Mediterranean region, South and Central America, malaria transmission is seasonal, with a low rate of natural immunity acquisition.[4] In these areas, adults and children are equally susceptible to severe malaria.

Pathophysiology

The incubation period typically lasts 7 to 14 days, although it could be longer in patients who have been treated recently with macrolides, trimethoprim-sulfamethoxazole, quinolones or tetracyclines. The sporozoites released following a mosquito bite reach the liver where they become hepatic merozoites. Once mature, they are discharged into the circulation where they invade the erythrocytes and form ring-like schizonts. [4] Infected red cells demonstrate altered adhesion and/or deformability characteristics that favour sequestration in the microcirculation. [5] This leads to microcirculatory occlusion, endothelial injury and intravascular haemolysis. The rupture of parasitised red cells causes the release of inflammatory cytokines as well as daughter merozoites which can infect new erythrocytes. Most manifestations of severe malaria are postulated to be due to cytoadherence of parasitised erythrocytes and microvascular occlusion (mechanistic hypothesis) and/or injury by malarial toxin and cytokines (cytotoxic hypothesis). Severe or complicated malaria with organ dysfunction occurs in *P. falciparum* infection with elevated parasitemia (>10% of erythrocytes infected), although ‘lower’ levels of parasitemia may be seen in some patients. [1] Severe malaria with *P. vivax* is infrequent since parasitemia is typically much lower (<1%).

Severe malaria

The World Health Organisation (WHO) 2023 guidelines [2] define severe falciparum malaria as the presence of one or more of the following features in the absence of an alternative cause and in the context of *P. falciparum* asexual parasitaemia (Table 21.1). Severe vivax malaria is defined as falciparum malaria but with no criteria for parasite density.

Table 21.1

Features of severe falciparum malaria

FEATURE	DESCRIPTION
Impaired consciousness	Glasgow Coma Scale score <11 in adults or a Blantyre Coma score <3 in children
Prostration	Generalised weakness so that the person is unable to sit, stand or walk without assistance
Convulsions	More than two episodes within 24 h
Acidosis	Base deficit of >8 mEq/L or, if not available, a plasma bicarbonate level of <15 mmol/L or venous plasma lactate ≥5 mmol/L. Severe acidosis manifests clinically as respiratory distress (rapid, deep, laboured breathing)
Hypoglycaemia	Blood or plasma glucose <2.2 mmol/L (<40 mg/dL)
Severe malarial anaemia	Haemoglobin concentration ≤50 g/L or a haematocrit of ≤15% in children <12 years of age (<70 g/L and <20%, respectively, in adults) with a parasite count >10,000/µL
Renal impairment	Plasma or serum creatinine >265 µmol/L (3 mg/dL) or blood urea >20 mmol/L
Jaundice	Plasma or serum bilirubin >50 µmol/L (3 mg/ dL) with a parasite count >100,000/µL
Pulmonary oedema	Radiologically confirmed or oxygen saturation <92% on room air with a respiratory rate >30/min, often with chest indrawing and crepitations on auscultation
Significant bleeding	Including recurrent or prolonged bleeding from the nose, gums or venepuncture sites; haematemesis

FEATURE	DESCRIPTION
	or melaena
Shock	*Compensated shock* defined as capillary refill ≥3 s or temperature gradient on leg (mid to proximal limb), but no hypotension. *Decompensated shock* defined as systolic blood pressure <70 mm Hg in children or <80 mm Hg in adults, with evidence of impaired perfusion (cool peripheries or prolonged capillary refill)
Hyperparasitaemia	*P. falciparum* parasitaemia >10%

From WHO Guidelines for Malaria, 14 March 2023. World Health Organisation; 2023 (WHO/UCN/GMP/ 2023.01). License: CC BY-NC-SA 3.0 IGO.

The risk factors for severe malaria include children under 5 years in high-transmission areas, people of any age in areas of low-transmission, non-immune travellers to endemic areas, pregnancy, human immunodeficiency virus (HIV) infection and people who have undergone splenectomy.

Diagnosis

Microscopic examination of thick and thin blood film smears remains the gold standard for the diagnosis of malaria. This enables the detection of the type of parasite, provides an estimation of parasitaemia and detects the presence of gametocytes. The absence of malaria parasites on a blood film does not rule out malaria; a subsequent examination may be performed 8 to 12 hours later if the index of suspicion of malaria is high.

The rapid diagnostic tests (RDT) are increasingly used for malaria diagnosis. These are either species-specific or pan-specific tests (such as Plasmodium lactate dehydrogenase (pLDH) or pan-specific aldolase). Pf-HRP2 test, a test with a high specificity for detecting falciparum infection, detects the presence of the *P. falciparum* histidine-rich protein. While these tests offer numerous potential benefits, such as the ability to quickly deliver results and expand diagnostic services to even the most basic healthcare facilities and communities with minimal training and expertise, there are some drawbacks. PfHRP2-based RDTs may not be able to differentiate between new and recently treated infections since PfHRP2 persists in the blood for 1 to 5 weeks after effective treatment. Additionally, varying frequencies of HRP2 deletions in *P. falciparum* parasites in the Amazon region render HRP2-based tests unsuitable in this area.[6] Furthermore, these tests exhibit poor sensitivity in detecting *P. malariae* and *P. ovale* .

Treatment

Severe malaria is a medical emergency. The fundamental tenets of management are similar to any other critically ill patient where the focus is on resuscitation and optimisation of the airway, breathing and circulation. This must be simultaneously accompanied by clinical evaluation, diagnostic tests, supportive treatment and anti-malarial therapy. Blood should be drawn for a full blood count, coagulation studies, cross-matching, blood culture and tests to evaluate renal and hepatic function. In patients with severe malaria, it may be prudent to add a broad-spectrum antibiotic since bacterial co-infections are reported to occur in 0.3% of travellers with malaria to 6.4% of African children with malaria.[7,8] A recent study from Myanmar reported a much higher incidence of bacteraemia of 14.9% in hospitalised adult patients with malaria.[7,9,10]

In endemic locations, severe malaria should be distinguished from bacterial sepsis, meningitis, encephalitis and other tropical diseases with similar symptoms, such as dengue, leptospirosis, rickettsial infections and enteric fever.

Anti-malarial therapy

The 2023 WHO guidelines recommend that ‘adults and children with severe malaria (including infants, pregnant women in all trimesters and lactating women) should be treated with intravenous or intramuscular artesunate for at least 24 h and until they can tolerate oral medication’.[11]

- Intravenous artesunate 2.4 mg/kg administered at 0, 12 and 24 h and then once daily for 7 days. For children weighing less than 20 kg, a dosage of 3 mg/kg is advised.
    - After a minimum of 24 hours of parenteral therapy and once the patient's ability to tolerate oral therapy has been established, it is recommended to conclude the treatment by administering an artemisinin-based combination therapy (ACT) for a duration of 3 days.
    - Artesunate must be dissolved in 5% sodium bicarbonate to form sodium artesunate. This solution is then diluted in about 5 mL of 5% dextrose and injected intravenously or intramuscularly into the anterior thigh.
- Re-evaluate parasite density at least 4 hours after the third intravenous dose of artesunate. After that, daily blood smears must be performed until smears are negative or until day 7 of treatment. Median parasite clearance times with artemisinin therapy is 72 hours; if parasitemia is not as clear as anticipated, consideration could be given to the administration of an alternative anti-malarial treatment for severe malaria.
    - For non-immune patients with parasite density >1% (at least 4 h after the third dose of parenteral therapy), intravenous therapy should be continued for up to six additional days until parasite density is <1%, at which point an oral regimen should be administered.
    - Patients in endemic regions who have received at least 24 h of parenteral therapy and are able to tolerate oral medications may transition to oral therapy even if parasitemia is greater than 1%.
- All hyperparasitaemic individuals must be monitored for late-onset anaemia till one month after therapy. Anaemia can occur over a week after initiation of artesunate. Artesunate exhibits a quick parasiticidal effect on ring-stage parasites, leading to their removal from red blood cells through the spleen. The delayed onset anaemia has been postulated to occur due to intravascular haemolysis of the re-introduced previously infected erythrocytes from the spleen.

- In cases where artesunate is unavailable, artemether is the preferred treatment option over quinine for malaria in both paediatric and adult populations.

Fluid therapy in severe malaria

This should be assessed individually, and it is not possible to give general recommendations on fluid resuscitation. Routine boluses of crystalloids or colloids are not recommended based on the findings of the FEAST study.[12]

Blood transfusion

The threshold for transfusion is largely based on expert consensus. Whole blood transfusion is recommended in patients with haemoglobin below 50 g/L and below 70 g/L in high- and low-transmission nations respectively.[2]

Exchange transfusion

Although there are potential benefits of exchange transfusion in severe malaria, in terms of reduction in parasite load in patients with high parasitaemia (>10%), lowering antigen and cytotoxin burden and improving microcirculatory abnormalities, there is insufficient evidence to recommend its routine use in severe malaria. Such benefits may be offset by the hazards of transfusion.

Cerebral malaria

This term is used when altered consciousness in malaria cannot be attributed to convulsions, sedatives, hypoglycaemia or a non-malarial cause. Stupor, coma, seizures, decerebrate posture and elevated intracranial pressure (ICP) are frequently observed.[4, 13] There is no evidence for prophylactic osmotic therapy or anti-seizure medications in cerebral malaria.[14] Prophylactic phenobarbital therapy in children is associated with an increased risk of respiratory arrest and hence should be avoided.[14]

Treatment should include measures to reduce ICP and cerebral metabolic rate of oxygen (CMRO) where indicated, by controlling fever, elevating the head end of the bed, management of seizures, osmotherapy and ventilatory strategies to temporarily reduce ICP.[15] High-dose dexamethasone is not advocated as it may extend the length of coma.[16]

Pulmonary involvement

Respiratory manifestations occur in approximately 25% of adults and 40% of children with severe falciparum malaria. Factors contributing to respiratory failure include respiratory compensation of metabolic acidosis, noncardiogenic pulmonary oedema, concurrent pneumonia and severe anaemia.[17] It must be kept in mind that acute respiratory distress syndrome (ARDS) can develop or worsen after the initiation of anti-malarial therapy.[18] Ventilatory strategies are similar to other aetiologies.[17]

Acute kidney injury and hepatopathy

Several factors contribute to acute kidney injury (AKI) in severe malaria and include decreased blood volume, shock, obstruction of the microcirculation and haemoglobinuria caused by intravascular haemolysis, particularly in patients with a high parasite index.[2] Renal replacement therapy is initiated as per standard ICU practices. Need for haemodialysis in patients with AKI may be required from about a third to 76% of patients.[19], [20] In patients with malaria hepatopathy, characterised by a three-fold increase in transaminase levels (alanine or aspartate) with or without conjugated hyperbilirubinaemia and no clinical or serological indication of viral hepatitis, glucose levels must be closely monitored and hypoglycaemia must be promptly corrected.[21] Management is mainly supportive.

Severe malaria in pregnancy

In severe malaria acquired during the second and third trimesters of pregnancy, the maternal mortality rate is approximately 50%, significantly higher than in non-pregnant adults. In all trimesters, pregnant women should therefore be initiated promptly on treatment with intravenous artesunate.[22] Premature labour and foetal mortality are common, and families should be counselled accordingly.

Severe vivax malaria

While *P. vivax* is considered to have a more benign course, severe disease has been reported from India where the predominant manifestations were thrombocytopaenia, renal and hepatic involvement in a third of patients and cerebral malaria in 9% of patients.[23] This has been attributed to comorbidities, *P. vivax* anti-malarial resistance, mixed falciparum and vivax infections and more virulent strains.[18], [24] The anti-malarial treatment is the same as for *P falciparum* malaria. *P. vivax* liver forms (hypnozoites) can survive for up to 10 years and produce blood relapses, hence Primaquine 15 mg/day for 14 days is recommended to prevent relapse. A single dose of tafenoquine 300 mg also prevents relapses.[25] While a recent meta-analysis, that pooled three studies, found no difference when tafenoquine was compared with Primaquine, the single-dose treatment is probably more practical than primaquine without increasing adverse effects in non-pregnant, non–G6PD-deficient people.[26]

Therapies that are not advised

Numerous adjunctive treatments have been evaluated in severe malaria but have not shown to be effective. These include heparin, prostacyclin, desferrioxamine, pentoxifylline, low-molecular-mass dextran, urea, high-dose corticosteroids, aspirin, anti-TNF antibody, cyclosporine A, dichloroacetate, adrenaline, hyperimmune serum, N-acetylcysteine and albumin bolus administration.[2]

Prevention of malaria

In addition to intermittent preventive treatment with either trimethoxazole-sulphamethoprim or sulfadoxine-pyrimethamine for high-risk groups, the WHO has authorised the RTS, S/ASO1 and R21/Matrix-M malaria vaccines, that target the circumsporozoite antigen on the surface of the *P. falciparum* sporozoite, to decrease global malaria load for children in high-transmission areas.[27], [28] Based on the available data, commenting on the efficacy of these vaccines is difficult. The utilisation of monoclonal antibodies, L9LS and CIS43LS, in malaria prevention represents an innovative strategy for delivering immune protection.[29] Although this is in the early phases of research, it could represent the way forward for protection against malaria.

Outcomes of severe malaria

Mortality in severe malaria ranges from 10% to 32%. Factors associated with a poor prognosis include shock, acute respiratory distress syndrome, bacterial coinfection, delay in diagnosis and in initiating anti-malarial therapy and lack of adequate intensive care facilities. [30]

Tuberculosis

Guidelines for the diagnosis and management of tuberculosis are regularly updated. The World Health Organisation guidelines comprise several modules and links can be found: https://www.who.int/publications/digital/global-tuberculosis-report-2021/featured-topics/tb-guidelines . These include consolidated guideline documents as well as operational handbooks.

Epidemiology

Tuberculosis (TB) continues to be a devastating disease worldwide. *Mycobacterium tuberculosis* infects one-third of the world’s population; each year about 10 million individuals develop active disease and 1.4 million die from the disease. Medical conditions that pre-dispose to TB include HIV infection, silicosis, diabetes, chronic renal failure/haemodialysis, malnutrition, solid organ transplant, gastrectomy, jejunoileal bypass, injection and inhalational drug abuse, alcoholism, chronic pulmonary disease and prolonged steroid use. Social factors such as institutional living conditions (nursing homes, homeless shelters and prisons), urban dwellings and poverty are associated with an increased risk of TB.

Pathogenesis

TB is usually caused by *M. tuberculosis* and four others (*M. bovis, M. africanum, M. microti* and *M. canetti*) grouped in the *Mycobacterium* complex. The genus *Mycobacterium* consists of many different species all of which appear similar on acid-fast staining.

Inhalation of tubercle bacilli leads to one of four possible outcomes: immediate clearance of the organism, primary or progressive primary disease, chronic or latent infection and reactivation disease. Latent infection refers to the presence of tuberculous infection (positive tuberculin reaction) without the disease.

The primary focus of infection is in the lungs which usually heal spontaneously. The primary infection is symptomatic in only 5% to 10% of adults with a higher incidence in children and those with HIV infection. It may present with hilar lymphadenopathy or with progressive pneumonic consolidation. Limited lymphohaematogenous dissemination commonly occurs during primary infection and leads to the silent seeding of multiple organs. These sites remain dormant (latent infection) but may become reactivated after a period of months to years. This is called secondary or reactivation TB. This is responsible for 90% of TB in patients not infected with HIV. Occasionally, lymphohaematogenous seeding may lead directly to disseminated miliary and meningeal disease.

Clinical Spectrum

The manifestations of TB are protean, and TB should be considered in the differential diagnosis of all patients with fever of unknown origin, night sweats or unexplained weight loss. Besides the lungs, it can also involve the central nervous system (CNS), peritoneum, pericardium, gastrointestinal and genitourinary tract, bone and joints, lymph nodes and skin. Occasionally it can be disseminated in the form of miliary TB.

Pulmonary tuberculosis

Pulmonary TB typically starts in the apex of one or both lungs as a small infiltrate. Progressive spread can lead to severe disease with extensive bilateral lung involvement characterised by infiltration, cavitation and fibrosis. Rupture of a lesion into the pleura may lead to spontaneous pneumothorax. Clinically, the patient presents with insidious onset of non-specific symptoms such as fever, night sweats, anorexia, weight loss and malaise. A cough develops and haemoptysis may occur. Dyspnoea is seen with more extensive disease. Sputum, induced sputum, bronchial washings and transbronchial biopsy of infiltrates should be examined to detect and isolate the organism. Computed tomography (CT) is more sensitive than chest radiography for the detection of infiltrates, cavities, lymphadenopathy, miliary disease, bronchiectasis, bronchial stenosis, bronchopleural fistula and pleural effusion.

Tuberculous pleural effusion

Pleural TB may result in pleural effusion, or pleural empyema with or without bronchopleural fistula. The pleural fluid should be examined for total protein and glucose content, white blood cell count and differential count and fluid pH. Positive fluid cultures are found in less than 25% of cases. Pleural fluid adenosine deaminase (ADA) levels more than 70U/L strongly favour tuberculous aetiology, and levels less than 40 U/L make it less likely. In populations with a high prevalence of TB and clinical suspicion, an elevated ADA level might be considered a confirmatory test justifying treatment initiation. [31] If the ADA level is more than 70 U/L and the lymphocyte percentage in the fluid is more than 75%, the diagnosis is virtually certain and pleural biopsy may not be needed. [32] Pleural biopsy may be required if the diagnosis is doubtful. Pleural biopsy shows granulomatous inflammation in approximately 60% of patients, and culture may be positive even in those without granulomas. When the culture of three biopsy specimens is combined with histologic examination, the diagnosis can be made in up to 90% of cases. Pleuroscopy-guided biopsies increase the yield in pleural sampling. Nucleic acid amplification (NAA) tests have high specificity but low and variable sensitivity.

Tuberculous Meningitis

Tuberculous meningitis remains the most serious manifestation of TB for the intensive care physician. It results from a haematogenous spread. [33] Pathologically there is a thick gelatinous exudate around the sylvian fissures, basal cisterns, brainstem and cerebellum. Classically it presents as a subacute meningitic illness. The majority of patients with TB meningitis have had recent contact with infectious TB, particularly during the preceding 12 months. A prodrome of vague ill-health lasting 2 to 8 weeks is commonly seen followed by signs and symptoms of meningeal irritation. Occasionally TB meningitis may present acutely without a prodromal period. Neck stiffness is usually absent during early disease.

Cranial nerve palsies occur in 20% to 25% of patients, and papilloedema may be present. There may be focal neurological deficits such as haemiplegia; extrapyramidal movements and seizures are other manifestations. Hydrocephalus and raised intracranial pressure may result from intracerebral exudates and inflammatory lesions impairing CSF resorption or obstruction at the cerebral aqueduct or fourth ventricle. As the disease progresses, cerebral dysfunction sets in and the mortality approaches 50%.

Both a diagnostic algorithm and consensus case definition have been published.[34], [35] However, the sensitivity and specificity of these diagnostic scoring algorithms have been found to be limited.[36] The key is a high degree of clinical suspicion especially in the critically ill.

Definitive diagnosis of TB meningitis depends upon the detection of the organism in the CSF, either by smear examination, nucleic acid detection or by bacterial culture. The yield from the smear is variable, but generally, sensitivity is low (approximately 30%). The sensitivity of CSF culture is 60% to 70% in adults and is considerably lower in children.[37] The sensitivity of the smear and culture may be increased by using the centrifuged deposit from a relatively large volume of CSF. Given the need for urgent diagnosis, GeneXpert MTB/RIF or GeneXpert MTB/RIF Ultra should be used in addition to conventional microscopy and culture on CSF specimens. These tests are discussed in a later section.

CT or magnetic resonance imaging of the brain, which is sensitive but not specific, may reveal thickening and intense enhancement of meninges, especially in basilar regions. Hydrocephalus and tuberculomas may also be present. Infarcts due to either vasculitis or mechanical strangulation of the vessels by the surrounding exudates are detected in up to 40%. The radiological differential diagnosis includes cryptococcal meningitis, cytomegalovirus encephalitis, sarcoidosis, meningeal metastases and lymphoma.

Tuberculosis may also present with other clinical emergencies such as massive haemoptysis, respiratory failure, pericardial tamponade, acute intestinal obstruction and status epilepticus. These require multidisciplinary care, evaluation and management in an ICU.

Diagnosis of tuberculosis

Once considered, isolate the patient and sample all potential sites for acid-fast staining and culture. Pleural, peritoneal, pericardial and other fluids must be cultured and analysed for differential cell count, protein, glucose and ADA. Involved tissues may be biopsied for histology and culture.

NAA tests amplify target nucleic acid regions that uniquely identify the *M. tuberculosis* complex, and are available as commercial kits or in-house assays. A sensitive and specific fully automated and commercially available NAA GeneXpert MTB/RIF and GeneXpert MTB/RIF Ultra assay can produce results in less than 2 hours permitting a specific TB diagnosis and rapidly detect rifampicin resistance. However, NAA tests cannot entirely replace conventional diagnostic approaches using microscopy and culture.

For GeneXpert MTB/RIF as an initial test replacing smear microscopy, a Cochrane review reported a pooled sensitivity of 89% and a pooled specificity of 99%. In sputum smear-negative specimens, the pooled sensitivity was lower at 67%; for people with HIV infection, the pooled sensitivity was 79%. [38]

Its performance in extrapulmonary TB is inferior and varies with sample type. [39] The pooled sensitivities were somewhat better with lymph node tissue or aspirate and significantly lower with pleural fluid. The pooled specificity was consistently over 98.7% against composite reference standards across different sample types. In CSF, the GeneXpert MTB/RIF Ultra has been found to have improved sensitivity (approximately 45%–75%) compared to the GeneXpert MTB/RIF (40%–56%) against a composite reference standard. [40]

The current status of NAA tests is summarised below:

- NAA tests, in general, have high specificity and positive predictive value; they are useful in ruling in rather than ruling out TB. Resources permitting, the WHO recommends the usage of GeneXpert MTB/RIF or MTB/RIF Ultra as the initial diagnostic test in sputum, CSF, lymph nodes and urine. [41] The GeneXpert MTB/RIF Ultra may not be widely available in low-income and middle-income countries.

- If clinical suspicion is high, TB is not excluded by both a negative smear and NAA. Empiric treatment for TB should be considered if clinical suspicion is high and the patient is critically unwell.

Drug susceptibility tests should be performed on initial isolates from all patients to identify an effective anti-tuberculous regimen. Some regions have moved to whole genome sequencing of isolates and inference of drug susceptibility according to genotypic features, which may offer a more rapid approach.

Treatment of tuberculosis

Local guidelines are of paramount importance and advice should be sought. [42] The commonest regimen used is isoniazid (5 mg/kg), rifampicin (10 mg/kg), pyrazinamide (1000–2000 mg daily depending upon body weight) and ethambutol (800–1600 mg depending upon the body weight) for the first 2 months and isoniazid and rifampicin for the next 4 months. Current clinical trials are investigating the role of higher doses of rifampicin (up to 35 mg/kg) and the use of levofloxacin and linezolid for the treatment of TB meningitis. Steroids are generally recommended for tuberculous meningitis and pericardial TB.

Drug-Resistant Tuberculosis

This is an increasing problem. Multidrug-resistant TB (defined as resistance to two or more of the first-line anti-tuberculous drugs, usually isoniazid and rifampicin) can be primary (no prior anti-tuberculous therapy) or secondary (development of resistance during or after chemotherapy). Extensively drug-resistant (XDR) TB, defined by additional resistance to one of the fluoroquinolones and one of the injectable drugs, is more difficult to treat and may be incurable.

Diagnosis depends upon the collection of adequate specimens for culture prior to the initiation of anti-tuberculous therapy. Recent studies have demonstrated the effectiveness of all oral, shorter course regimens for multidrug-resistant (MDR) or extensively drug-resistant (XDR) TB. The WHO now recommends as first line a 6-month bedaquiline, pretomanid, linezolid and moxifloxacin (BPaLM) regimen. The recommendation of the BPaLM regimen applies to people with pulmonary TB and all forms of extrapulmonary TB except for TB involving the CNS, and osteoarticular and disseminated (miliary) TB (due to a paucity of data in those populations). Expert advice should be sought for treatment in those with TB involving the CNS, and osteoarticular and disseminated (miliary) TB. [43-45]

Management of TB meningitis

There are several neurocritical care issues relevant to TB meningitis. [46] Initiation of treatment should not be delayed pending a definitive diagnosis where there is reasonable clinical suspicion and epidemiological risk for TB meningitis. Complications include hydrocephalus and raised ICP, cerebral infarction, tuberculomas that may exert local mass effect, hyponatraemia and paradoxical reactions while on anti-tuberculous chemotherapy. It is therefore critical to provide appropriate supportive care, with a particular focus on monitoring and safely reducing intracranial pressure while antituberculosis chemotherapy takes effect.

Glucocorticoids are recommended for patients with and without HIV. These should be given for a 6 to 8-week tapering regimen, commencing with dexamethasone 0.3 to 0.4 mg/kg IV daily (or oral prednisolone 0.5 mg/kg up to 40 mg per day) for adults.

Cholera

Cholera is an acute diarrhoeal illness caused by toxin-producing strains of *Vibrio cholera* . The incubation period varies from a few hours to 5 days and depends on the inoculum size and host factors such as hypochlorhydria, which lowers the infectious dose required to produce disease and O blood type and partial gastrectomy which pre-dispose to more severe infection. [47], [48] The clinical case: infection ratio is about 1: 10. Severe cholera or cholera gravis is characterised by the passage of large volumes of painless fishy-odour loose stools with flecks of mucus-typically described as ‘rice-water stools’, with or without vomiting. Stool output can be as high as 1 L/h in the most severe cases, with losses of higher concentrations of electrolytes and bicarbonate when compared with other causes of diarrhoea. Fever is classically uncommon. The clinical progression of the condition can range from mild diarrhoea to serious consequences such as hypokalaemia, hyponatraemia or hypernatraemia, hypocalcaemia, metabolic acidosis and acute renal injury that may warrant ICU admission and management. Among these complications, untreated electrolyte imbalance, metabolic acidosis and AKI can result in death.[49]

The gold standard for diagnosis is stool culture using selective media; in non-endemic areas, the lab must be alerted if there is a clinical suspicion of cholera to ensure the use of the appropriate culture media. Commercial cholera tests, Crystal VC and Cholkit, use rapid antigen detection techniques and can detect the O1 or O139 antigen in watery diarrhoeal faeces with a reported sensitivity and specificity of 90% and 86% respectively.[50] Dark field microscopy examination of fresh stool, a test with reasonable specificity but low sensitivity, may reveal rapidly motile comma-shaped bacilli.

Aggressive rehydration is the mainstay of treatment; patients with severe cholera, where the volume loss may be >10% of the body weight, can have a fluid deficit of close to 100 mL/kg. Adjunctive antimicrobial therapy, either doxycycline 300 mg as a single dose or azithromycin 1 gm as a single dose, shortens the duration of diarrhoea, reduces stool volume by up to 50% and reduces the duration of *V. cholerae* shedding to one to two days when compared with fluoroquinolones and trimethoprim-sulphamethoxazole.[51]

Leptospirosis

Leptospirosis is a zoonotic disease with diverse clinical manifestations induced by pathogenic Leptospira spirochetes that include *Leptospira interrogans* , *L. weilii* and *L. borgpetersenii* . The disease is sporadic in humans although outbreaks can occur after exposure to common sources. It is prevalent in South and Southeast Asia, Oceania, the Caribbean, parts of sub-Saharan Africa and parts of Latin America. Humans are incidental hosts and are infected after exposure to the urine of infected mammals (usually rodents) or to environmental reservoirs. At-risk people include farmers, veterinarians and low socioeconomic status individuals. Infection can occur following recreational activities such as freshwater swimming or gardening or after travel to endemic areas during heavy rainfall or flooding. Transmission occurs through cuts or abrasions in the epidermis, mucous membranes and conjunctivae.

Clinical manifestations and differential diagnosis

The incubation period is 2 to 30 days. The illness is characterised by two phases, anicteric and icteric phases. The anicteric syndrome has an *acute febrile phase* that mimics other infections, which is rarely followed by an *immune phase* , characterised by aseptic meningitis and uveitis. Acalculous cholecystitis and pancreatitis have been reported in children. Conjunctival hyperaemia without purulent discharge is seen in most patients. Maculopapular skin rash may be seen in 10% to 40% of patients. The icteric leptospirosis is seen in 5% to 10% of patients. Patients present with icterus and renal failure, a syndrome called Weil’s disease. ARDS, pulmonary haemorrhage and rhabdomyolysis are also common. Conjunctival suffusion can be seen in this stage as well. AKI with renal failure, ARDS with pulmonary haemorrhage, disseminated intravascular coagulation (DIC) and multi-organ dysfunction syndrome (MODS) are common reasons for admission to the ICU. [52]

Leptospirosis must be distinguished from other causes of acute febrile illnesses such as malaria, dengue, typhus, typhoid fever, hepatitis A and haemorrhagic fevers as well as non-infectious causes that include vasculitic pulmonary renal syndromes.

Various scoring systems have been described for risk stratification of leptospirosis. Faine’s criteria, which were among the initial criteria to be proposed in 1982, encountered limitations in low-income countries due to their reliance on the microscopic agglutination test, thereby diminishing their practical application. Smith et al. in Australia created the SPiRO score, a three-point score based on systolic blood pressure ≤100 mm Hg, respiratory auscultation abnormalities and oliguria. Each component received one point. A score of <1 in SPiRO has a 97% negative predictive value for severe illness and this score outperformed qSOFA in the emergency department. [53]

Management

The diagnosis of leptospirosis is confirmed by either a positive PCR in blood or by a positive serologic test. Decision on the type of test is dependent on timing of sample with reference to onset of symptoms. Blood PCR is more likely to be positive in the first week of illness, while antibodies are positive in the second week of illness. Negative test findings do not rule out the diagnosis because of the moderate sensitivity of leptospirosis testing. A single positive or negative IgM or IgG test on the microscopic agglutination test (MAT) or ELISA cannot confirm or rule out infection and it is recommended that a second sample be sent 7 to 10 days later. Blood cultures are rarely used for confirmation of the diagnosis since it can take 1 week to 3 months to grow the organism in culture and furthermore specialised media must be used.

Recently, the BioFire Global Fever Panel (GF Panel), a multiplex NAA assay on whole blood specimens run on the BioFire FilmArray System, has been shown to diagnose numerous acute febrile disease pathogens within an hour of sampling with excellent positive and negative agreement. Leptospira species is one among the six analytes that can be identified using this test. Other species that were identified with this assay include Chikungunya virus, dengue virus and the *Plasmodium* species (*falciparum*, *vivax* and *ovale*). This assay is hence valuable for both individual diagnosis and public health surveillance due to its quick turnaround time and excellent agreement. [54]

Patients with mild disease can be treated with oral doxycycline 100 mg twice daily for 7 days or azithromycin 500 mg once daily for 3 days. For hospitalised adults with severe disease, therapeutic options include 7-day treatment with penicillin (1.5 million units intravenously [IV] every 6 hours), doxycycline (100 mg IV twice daily), ceftriaxone (1 to 2 g IV once daily) or cefotaxime (1 g IV every 6 hours). IV Doxycycline is preferred if rickettsial infection is one of the differentials. Patients with severe leptospirosis may require organ support in the form of ventilatory support, renal replacement treatment and blood products. [55] There are some reports that suggest a role for steroids in severe leptospirosis given the possible vasculitic nature of the manifestations; however, the evidence is insufficient to support its use. [56]

Outcome

Mortality ranges from 6% to as high as 52%. [57] Haemorrhagic ARDS, acute renal failure, DIC, severe metabolic acidosis, older age, chronic alcohol abuse, a high SOFA score and septic shock are poor prognostic indicators.

Hantavirus infections

The hantaviruses are a large group of rodent-carried viruses found across the globe. [58] A proportion is associated with human disease, which presents as two distinct severe febrile illnesses: haemorrhagic fever with renal syndrome (HFRS) and hantavirus cardiopulmonary syndrome (HCPS). Both are typically acquired by exposure to aerosols of rodent excreta or secretions, most commonly in poorly ventilated indoor environments.

Haemorrhagic Fever with Renal Syndrome

HFRS is characterised by fever, hypotension, AKI and haemorrhagic manifestations. The disease has five progressive stages: febrile, hypotensive, oliguric, diuretic and convalescent. Non-specific constitutional symptoms are followed by shock, oliguria, DIC and haemorrhagic manifestations. Respiratory failure may also occur. Laboratory findings of leukocytosis, thrombocytopaenia, elevated CK and creatinine with proteinuria and haematuria support the possibility of HFRS. Diagnosis is made using serological testing for IgG and IgM antibodies. Treatment is supportive, including renal replacement where indicated. Ribavirin has been shown to reduce mortality in some studies. [59] Mortality rates are estimated to be 1% to 10% depending on the causative virus. [60]

Hantavirus cardiopulmonary syndrome

HCPS commonly manifests in two distinct clinical phases following an incubation period of 2 to 3 weeks: the prodromal phase is characterised by a relatively mild febrile illness, typically lasting 2 to 8 days with myalgia, gastrointestinal upset and headache. The cardiopulmonary phase follows, typified by severe, rapidly progressive respiratory failure with haemodynamic compromise and coagulopathy. Progress from the prodromal phase to the cardiopulmonary phase is rapid. Acute pulmonary oedema occurs due to increased capillary permeability, with significant myocardial depression in severe cases, resulting in shock due to low cardiac output. Acute renal failure can occur. A combination of thrombocytopaenia, myelocytosis, haemoconcentration, lack of significant toxic granulation in neutrophils and immunoblastic morphology of more than 10% of lymphocytes is highly sensitive and specific. Serum lactate, lactate dehydrogenase and liver enzyme levels may also be elevated. Serological testing for IgM and IgG antibodies is the predominant method for diagnosis. Treatment is mainly supportive with mechanical ventilation, early use of cardiovascular support and careful administration of intravenous fluids and blood products. Extracorporeal membrane oxygenation may be effective in the most severely affected patients. [61] There is no role for ribavirin therapy, despite its potential utility in HFRS, but a role for monoclonal antibody therapy is proposed. [62] Mortality rates are estimated to be as high as 50% depending on the causative virus. [61]

Arboviral Encephalitis

Encephalitis has a wide range of infectious and autoimmune causes, and the aetiology can be difficult to establish due to overlap in clinical features, CSF findings and imaging appearances. [63] Viruses transmitted to human beings by the bites of arthropods (especially mosquitoes and ticks) are major causes of encephalitis worldwide. Although numerous viruses can cause encephalitis, an antigenically related group of flaviviruses accounts for a major proportion of cases.[64] These include mosquito-borne diseases such as Japanese encephalitis, West Nile virus encephalitis, St. Louis encephalitis, Murray Valley encephalitis and tick-borne encephalitis.[65], [66] Viral encephalitis is characterised by an incubation period of 5 to 15 days, followed by a non-specific prodromal illness. The classical triad of fever, headache and altered level of consciousness then ensues. Additional neurological features are disparate and can include disorientation, behavioural and speech disturbances, focal signs such as haemiparesis, and seizures, including status epilepticus. A flaccid paralysis resembling that of poliomyelitis and Parkinsonian-type movement disorders may also be observed. Patients commonly have non-specific markers such as raised serum white cell count, hyponatraemia, thrombocytopaenia and abnormal liver function tests. CSF is typically lymphocytic with slightly elevated protein. Lumbar puncture opening pressure may be elevated. CT/MRI and EEG may show non-specific abnormal features. Definitive diagnosis of flavivirus encephalitis is by detection of virus-specific IgM in serum or CSF. With extended testing panels, based on standardised algorithms, identification of a causative agent is improved more than three-fold for all causes (40% vs. 13%). Half of cases diagnosed on extended testing are arboviral.[67] Treatment is supportive. Interferon-α, ribavirin and intravenous Ig have all been tried with mixed success but all lack sufficient evidence to recommend. Outcome varies with cause, with mortality as high as 30% in some viral types and up to 50% of survivors experiencing significant neurological sequelae.

Rickettsial infections

The non-epidemic rickettsial infections comprise scrub typhus, murine typhus and the spotted fever group rickettsioses. Scrub typhus is a mite-borne disease caused by *Orientia tsutsugamushi*. It is widespread in the Indian subcontinent, southeast Asia and northern Australia. Murine typhus is a flea-borne disease caused by *Rickettsia typhi*. It has a worldwide distribution: Africa, Southeast Asia and South Asia being common sites of disease acquisition in returning travellers. The spotted fever group rickettsioses are predominantly tick-borne. *R. rickettsia* causes Rocky Mountain Spotted Fever, which occurs throughout the Americas. *R. conorii* causes Mediterranean spotted fever which occurs predominantly in the Mediterranean, Africa and the Indian subcontinent. *R. africae* causes African tick typhus or African tick bite fever seen in sub-Saharan Africa. All rickettsial infections require early diagnosis and treatment as delay is a strong predictor of poor outcomes.

Rickettsial infections present variably and non-specifically, commonly with fever, headache, gastrointestinal symptoms and myalgia. Rash is common and is usually maculopapular. An inoculation site eschar is characteristic in scrub typhus, African tick bite fever, Mediterranean spotted fever and others but is not ubiquitous. Respiratory symptoms, meningoencephalitis, hepatomegaly and splenomegaly, AKI and localised or generalised lymphadenopathy may occur in severe cases. Myocarditis and pneumonitis may develop, progressing to multi-organ dysfunction, especially if treatment is delayed.

Leukopaenia or leucocytosis may occur, while thrombocytopaenia and elevated transaminase levels are common. CSF may show lymphocytic pleocytosis and elevated protein. Diagnosis is suspected on clinical grounds and a dramatic response to antimicrobial therapy is supportive. Definitive diagnosis is challenging and can be confirmed by antibody detection, PCR, culture or skin lesion biopsy in specialised laboratories. First-line treatment for all rickettsioses is with doxycycline. Azithromycin is an alternative in all but RMSF. Combination therapy may be superior in severe scrub typhus. Administration of doxycycline and azithromycin in severe scrub typhus results in a lower incidence of persisting organ dysfunction at seven days than monotherapy with either agent, although 28-day mortality is unchanged. [68] Early administration is associated with reduction in organ dysfunction and mortality. Overall mortality may be up to 6% in scrub typhus (up to 70% in severe disease) but is probably closer to 1% in the other rickettsioses.

Dengue fever

Epidemiology and pathogenesis

The WHO estimates that 390 million dengue infections occur annually with close to 100 million clinical infections 70% of this burden is in Asia.[69, 70] The causative agent is a flavivirus with four distinct serogroups, which is transmitted by the bite of Aedes mosquitoes. Two patterns of transmission have been recognised: epidemic due to isolated introduction of dengue to a region, usually due to a single serotype; and hyper-endemic referring to the continuous circulation of multiple dengue virus serotypes.[69, 70]

Following a mosquito bite, viraemia begins and usually lasts up to 7 days. Infection with one of the four serotypes (primary infection) provides life-long immunity against that serotype but not against the other serotypes (secondary infection). Epidemiological studies have suggested that the risk of severe disease is significantly higher in secondary infection than in primary infection.

Clinical features

Dengue virus infection may be asymptomatic or may progress through three stages, a febrile phase and the critical and convalescent phases.[71, 72] Dengue fever (DF) has an incubation period of 3 to 14 days and is characterised by the sudden onset of fever, severe headache, retro-orbital pain on moving the eyes and fatigue. The fever usually lasts for 2 to 7 days. It is often associated with severe myalgia and arthralgia (breakbone fever). Maculopapular rash, flushed facies and injected conjunctiva are common. Haemorrhagic manifestations can occur in DF and do not necessarily mean dengue haemorrhagic fever (DHF).

DHF occurs primarily in children younger than 10 years old and is characterised by plasma leakage syndrome as evidenced by haemoconcentration (20% or greater rise in haematocrit), pleural effusion or ascites. The diagnosis is made if all of the following symptoms and signs are present: bleeding or positive tourniquet test, a platelet count of less than 100,000 per cubic millimetre and plasma leakage. Haemorrhagic manifestations without evidence of plasma leakage do not constitute DHF. The mechanism underlying the profound capillary leak in DHF but not in DF is poorly understood. It is important to watch for the onset of DHF, which typically occurs 4 to 7 days after the onset of the disease, approximately at the time of defervescence. A decrease in the platelet count and a rise in haematocrit are useful clues. [73]

Due to the limitations of the 1997 WHO classification, a new classification was adopted by them in 2009 [74] :

- Dengue without warning signs
- Dengue with warning signs
- Severe dengue

Warning signs include any one of abdominal pain or tenderness, persistent vomiting, clinical fluid accumulation, mucosal bleed, lethargy, restlessness, liver enlargement greater than 2 cm, laboratory: an increase in haematocrit, concurrent with a rapid decrease in platelet count.

Criteria for severe dengue include any one of:

1. Severe plasma leakage leading to shock (DSS) or fluid accumulation with respiratory distress
2. Severe bleeding as evaluated by the clinician
3. Severe organ involvement (any) such as liver (aspartate aminotransferase [AST] or alanine aminotransferase ≥ 1000U), CNS (impaired consciousness), heart and other organs referred to as expanded dengue syndrome.

Diagnosis

Dengue should be suspected in all febrile patients who live in, or have returned from, endemic areas in the preceding 2 weeks. Leukopaenia, thrombocytopaenia with a positive tourniquet test and raised AST are frequently seen; the former two tests have the highest sensitivity (about 90%) for the diagnosis of early dengue. [71-73] A positive tourniquet test alone cannot differentiate DHF from DF.

IgM immunoassay allows rapid confirmation of the diagnosis. If it is negative, particularly in the first 6 days of the illness, the diagnosis should not be ruled out. Acute and convalescent sera should be analysed by immunoassay or haemagglutination assay to demonstrate seroconversion or a fourfold rise in titer.

Virus isolation, viral nucleic acid detection by techniques such as reverse transcriptase PCR and viral antigen detection are the other diagnostic tests available. The dengue NS1 antigen test has a high specificity (93%–100%). It is very useful for early diagnosis before the antibodies become positive. Sensitivity is highest on day 1 of the illness and declines gradually over time, and is 45% to 57% at the time of hospital admission. [75]

Treatment

Unfortunately, despite the burden of disease, there are no specific treatments available currently. Supportive therapy for shock, especially appropriate and prompt fluid replacement, can reduce mortality. There is currently no role for prophylactic platelet transfusions. [76] Fluid management is complex and WHO guidelines are available. [77] While there are potentially promising therapeutic options, high-quality multi-centre trials are urgently needed to confirm efficacy and safety. [78], [79]

Tetanus

Epidemiology

The incidence and mortality rate of tetanus disease decreased significantly worldwide from 1999 to 2019. [80] However, the number of cases and deaths in low and middle-income countries are higher than in high-income countries. [80] Most of the tetanus cases in low and middle-income countries are in 0- to 14-year age group, especially newborns (neonatal tetanus), while in high-income countries they are predominantly in the elderly. [80] Rural areas with poor hygiene, poor medical facilities, limited vaccination programmes and high rates of manual work have high incidence and mortality rates.

Pathogenesis

C. tetani is an obligate anaerobic, Gram-positive bacillus. The bacteria exist in two forms: vegetative and sporulated form. Spores are resistant forms of bacteria and exist in soil, water, dust, in animal and human faeces. After accessing devitalised tissue through breaks in the skin, in anaerobic conditions, spores germinate and bacteria replicate and produce toxins. [81], [82] Tetanus toxin causes the specific symptoms of tetanus. [82]

Common sites by which *C. tetani* spores access the human body (entry sites) are skin wounds, scratches/abrasions, punctures, burns, open fractures, cut the umbilical cord by non-sterile equipment, chronic dermatitis, ulcers, otitis media and even surgery. The injury maybe small, and approximately 20% have unknown entry sites. [83], [84]

The transport of tetanus toxin from wounds to the CNS is complex. [82] Tetanus toxins diffuse via the bloodstream, enter motor neurons, then via retrograde axonal transport move to the anterior horn of spinal cord and then to inhibitory cell of CNS. Its principal effect is to block γ-aminobutyric acid (GABA) transmission, leading to impaired inhibition of muscle contractions causing continuous muscle contractions and increasing muscle tone. Tetanus toxin disrupts multisynaptic reflexes in the spinal cord and increases sensitivity to stimuli. Tetanus cannot spread from person to person. [85]

Immunoprophylaxis and risk of infection

People who were not immunised, partially immunised or fully immunised but without booster doses are at high risk of infection. The protective effect of antitoxin is still controversial.

After recovery from tetanus, patients have no natural antibody to protect them from relapse or recurrence and active vaccination schedules should be performed (i.e. primary and booster vaccinations). [81]

Infants born to women with insufficient or incomplete tetanus vaccination and where aseptic techniques were not used during delivery are at high risk of getting disease. [86], [87]

Clinical presentation

The incubation period (time from injury to the first symptoms) is on average 3 to 21 days.[85,88] It is at times difficult to determine the incubation period due to unknown wound entry. The hallmark of tetanus is muscular spasms which may continue up to 4 weeks.[89] Shorter duration of incubation and the onset period related to worse prognosis.[90] The severity of tetanus also varies, depending on the amount of toxin that reaches the CNS.

There are four types of clinical presentations: generalised, localised, cephalic and neonatal tetanus.[85] Generalised tetanus is the most common manifestation.[88] The first symptom of tetanus is lockjaw or trismus, dysphagia. In severe cases, the clinical presentation progresses with risus sardonicus and back extensor muscle spasm (opisthotonos). Some other postures were documented but rarely seen in clinical practice such as embrosthotonos (forward bending), orthotonus (straight posture) or pleurosthotonus (lateral bending).[91]

Spasms (local or generalised) occur spontaneously or can be provoked by external stimuli (e.g. noise, pressure and light). Pharyngeal spasms and laryngospasms can be life threatening causes of airway obstruction resulting. Importantly, patients are always conscious throughout.

Local tetanus is characterised when spasms or rigidity occur in one area of the body only, occurring in the limb with the originating wound.

Cephalic tetanus usually results from head and neck injuries, eye infections and otitis media. It can be associated with cranial nerve palsy and is important to monitor as can rapidly progress to pharyngeal/laryngeal spasm and airway complications.[88] This type of tetanus sometimes makes misdiagnosis with stroke a might develop generalised manifestation.[87]

Neonatal tetanus is usually of a generalised type, occurring from day 3 to 28 of life and usually secondary to umbilical cord infection.[88] Initial manifestations are weakness and difficult to suck, poor feeding followed by generalised spasms and opisthotonos similar to described earlier.[88,92]

Ablett classification of severity of tetanus [93]

Autonomic nervous system dysfunction (ANSD) occurs in very severe cases usually after the first week of symptoms, although may be up to the third week of disease (Table 21.2).[90, 94, 95] There is no specific definition of autonomic nervous system disturbance but clinical symptoms include fluctuation of heart rate (tachycardia or bradycardia) and fluctuation of blood pressure (hypertension or hypotension), believed to result from alterations in sympathetic or parasympathetic nervous system activities. Increased plasma and urine concentrations of adrenaline or noradrenaline are associated with clinical features of ANSD.[96] Fever without any other reasons is sometimes found in ANSD and may result in hyper-pyrexia which is difficult to control by normal treatments such as antipyretic, anti-inflammatory drugs or active cooling. Hyperpyrexia should be treated aggressively to prevent complications associated with hyperthermia.[97, 98]

Table 21.2

Ablett classification of severity of tetanus

GRADE	SEVERITY	SYMPTOMS
I	Mild	Mild trismus, general spasticity, no respiratory compromise, no spasms, no dysphagia
II	Moderate	Moderate trismus, rigidity, short spasms, mild dysphagia, moderate respiratory involvement, respiratory rate >30 breaths/min
III	Severe	Severe trismus, generalised rigidity, prolonged spasms, severe dysphagia, apnoeic spells, pulse >120 beats/min, respiratory rate >40 breaths/min
IV	Very severe	Grade 3 with autonomic dysfunction

Diagnosis

There is no confirmatory laboratory test to diagnose tetanus. The diagnosis is based on typical symptoms and clinical features.[88, 90, 99] *C. tetani* can be cultured from stools, and from known and unknown entry. However, positive culture of *C. tetani* from wounds cannot confirm a diagnosis of tetanus nor does a negative culture exclude the diagnosis. [90]

Typical clinical diagnosis based on [90, 100]:

- Have entry sites and suspected sources of infection
- Trimus or lockjaw
- Specific muscle rigidity
- Muscle spasms (localised or generalised)
- Pharyngeal spasm
- Laryngospasm
- Cyanosis, apnoea
- ANSD

Differential diagnosis includes [90, 100, 101]:

- Dental infections
- Intraoral diseases
- Peritonsillar infections
- Submaxillary lymphadenitis
- Cranial nerves diseases
- Brain tumour
- Meningitis
- Encephalomyelitis
- Encephalitis
- Intracranial haemorrhage
- Hypoglycaemia
- Hypocalcaemia
- Peritonitis
- Acute abdominal emergencies
- Histeria
- Seizure
- Stiff person syndrome
- Neuroleptic malignant syndrome

- Strychnine poisoning; narcotic/drug withdrawal, serotonin syndrome

Neonatal tetanus: differentiate with sepsis, brain haemorrhage, meningitis.

Complications

Respiratory complications	Respiratory failure, pneumonia emboli
Cardiac complications	Cardiac arrest, myocardial impairment, ischaemic heart disease
Nervous complications	Nerve palsy
Complications related to ICU stay	Stress ulcers, pressure sores
Muscle	Muscle weakness
Other complications	Tracheostomy complications, gastrointestinal bleeding, complications due to malignant hyperthermia, deep vein thrombosis

Management

Ideally, patients with tetanus should be monitored and treated with intensive care facilities to enable rapid intervention and optimal management of airway, respiratory and cardiovascular complications of the disease. The principles of treatment are early recognition of tetanus, neutralisation of any circulating toxin, eradication of the source of toxin, control of signs through appropriate supportive care and finally prevention through active immunisation. [102]

Passive immunisation

Human tetanus immune globulin (HTIG)is the recommended preparation in most high-income settings (usually recommended as an intramuscular injection). According to the guidelines from the Centres for Disease Control and Prevention, an intramuscular dose of HTIG of 500 units should be given.[89] This dose provides similar effect to higher dose of 3000 to 6000 units intramuscular.[88, 103]

In low and middle incomes countries, equine tetanus antitoxin is still commonly used with similar outcomes to human antitoxin.[104, 105] Historically, concerns about allergic reactions with the use of equine antitoxin have been cited, but the most recent data do not support this.[105]

Similarly, for equine antitoxin, different dose regimens have been recommended. For instance, the guidelines from India have suggested a dose of 10,000 to 20,000 units, while the recommendation from Vietnam is a single dose of 21,000 international units for adults.[95]

A randomised control trial in Vietnam showed that there were no significant differences in terms of ventilation support, complications, hospital stay and outcomes between two groups who used equine (21,000 international units) and human tetanus antitoxin (3000 international units).[105] The addition of intrathecal antitoxin does not provide more benefit than intramuscular antitoxin.[105]

If HTIG and equine antitoxin are not available, clinicians can use intravenous immunoglobulin (IVIG) with a dose of 200 to 400 mg/kg.[103] However, the use of IVIG remains controversial.[103]

Eradication of the organism

Wound care

Wound debridement should be performed after giving antitoxin to prevent the release of tetanus toxins during the procedure.[106] Analgesic drugs can be used to reduce pain.

Antibiotics

Metronidazole is preferred antibiotic for tetanus. Dose recommendations are 30 mg/kg/day for children and 500 mg × 3 times/day for adults. The duration of antibiotic use is 7 to 10 days, depending on the wound.[102, 107] Penicillin G: 100,000 – 200,000 UI/kg/day in 10 to 14 days is an alternative. However, there are concerns penicillin may cause muscle spasms because it has same structure as GABA and seems to eradicate *C. tetani* slower even with high dose.[102, 108-110]

Supportive care

Control of spasms

Tetanus patients can tolerate large doses of sedation to control spasms **and benzodiazepines are the drug of choice.** Optimal dose is the lowest dose that can control spasms and dose not depress the circulatory and respiratory functions. The dose should be decreased in elderly patients who have liver diseases. High doses of diazepam should be avoided because this drug might cause hyperosmolarity and lactic acidosis.[111] Midazolam, a short acting benzodiazepine, is a better option for tetanus with less side effects. Intermittent intravenous bolus dose can be given if necessary.[95, 107]

Neuromuscular blocking agents

Neuromuscular blocking agents are required in severe diseases where muscle spasms are not controlled by sedation alone. Depending on available drugs, pipecuronium, atracurium, rocuronium, vecuronium or pancuronium can be used. Pancuronium has however been documented to worsen the autonomic nervous disturbance.[87]

Magnesium sulphate, a calcium-antagonist, also has been used in tetanus in conjunction with other muscle relaxants to control spasms.[107] The use of barbiturates like Phenobarbital or Chlorpromazine is not common and has not been used as the first choice of drugs.[102]

A point of caution is that neuromuscular blockage is not safe when using without ventilatory support.

Management of autonomic dysfunction

The rapid fluctuation of cardiovascular parameters makes ANSD difficult to control. Magnesium sulphate reduces adrenal medullary adrenalin release and is used to control high blood pressure and tachycardia. [112] Studies have aimed for serum concentrations of 2 to 4 mmol/L with or without a loading dose. [107], [113] Additional strategies include beta-blockers (labetalol, propranolol and esmolol), calcium antagonists and opioids with strict monitoring. In case of persistent hypotension, vasopressors should be used to stabilise the haemodynamics.

Support respiratory failure

Airway management in tetanus can be challenging due to easily provoked laryngeal spasms and excessive secretions. Many centres advocate tracheostomy as first-line airway management due to risk of laryngeal spasms during intubation and prolonged mechanical ventilation. [87] Prolonged hospitalisation and ventilatory supports may cause ventilator-acquired pneumoniae.

Other supportive measures

Early nutritional support is required. Enteral feeding is preferrable. In the cases of poor feeding, a nasogastric tube is indicated.

Early prophylaxis of deep vein thromboembolism with low molecular heparin, heparin or intermittent pneumatic compression in case of contraindication to the use of heparin.

Finally, a full course of tetanus toxoid-containing vaccine should be given, following local recommendations.

Severe soft-tissue infections

Paul B. Bartley and Carl Joseph Lisec

Introduction

The human integument, the largest of the bodily organs, represents a major interface and barrier between an individual and their environment. It maintains critical roles in thermoregulation, innate and adaptive immune responses, sensory regulation and hormone metabolism. The ecological niche that human skin provides its microbiota, facilitates a symbiotic relationship where the normal flora facilitates colonisation-resistance to human pathogens. There is also emerging evidence of a role for the cutaneous microbiota both in wound healing and possibly modulation of human immune responses. This chapter will focus on the diagnosis and treatment (medical and surgical) of severe primary skin and soft-tissue infections of importance to critical care specialists; with less emphasis on cutaneous manifestations of severe disease originating elsewhere.

Epidemiology and Pathophysiology

Severe skin and soft-tissue infections (SSTI) represent a diverse group of infections with varying epidemiology and pathophysiology. SSTI comprise approximately 5% of severe sepsis hospital presentations and an incidence of 115/100,000 per year based on a series of long-term, prospective European studies. [1] Invasive Group A *Streptococcus* (iGAS) bloodstream infections alone account for >600,000 annual cases and >160,000 annual deaths globally, with a greater burden of disease and disability-adjusted life years (DALYs) lost due to the less immediately life-threatening manifestations of this infection.[2,3] The 30-day mortality of SSTI has been estimated at between 3% and 20%.[4] Significant risk factors for infection include penetrating trauma, macro- and microvascular ischaemia, burns, oedema, pressure injuries, injecting drug use, trauma contaminated with foreign material and immunosuppression due to illness, therapy or age. Co-incidental infection at other sites in association with severe SSTI is associated with increased mortality.[4]

Classification

There is no universally agreed-upon classification system for SSTI. This group of infections includes any with a component of necrosis involving the dermis, subcutis, deep fascial layer and muscle. Classifications have included pathophysiological (hospital gangrene), anatomical (necrotising cellulitis or fasciitis), microbiological (Streptococcal or Clostridial gangrene) and eponymous (e.g. Fournier's gangrene) denotations.[5] Regardless of classification, there are broad pathophysiological and management similarities across the infections which cause necrotising SSTI, and it is essential that the attending physician recognises infections with a necrotising component rapidly; as they constitute a surgical (and often critical care) emergency.

Microbiology

Constitution of the normal human microbiota commences at birth and continues to evolve across the lifespan. The normal human cutaneous microbiota includes bacteria, fungi and viruses. It varies according to body region, moisture and oil content of the skin, chronological ageing and photo-ageing. Significant changes occur in response to sex hormone changes of puberty. Commensal skin organisms include many species from the bacterial genera *Cutibacterium, Corynebacterium, Micrococcus* and *Staphylococcus* , among many others. Enterobacterales are more represented on the lower limbs. Thirty percent of humans have cutaneous or nasal carriage of *Staphylococcus aureus* . Commensal fungal species include members of the *Malassezia, Rhodotorula, Aspergillus* and

Epicoccum genera. Cutaneous dysbiosis is a reported consequence of ageing and diabetes mellitus and may predispose to delayed wound healing. *Enterobacterales* are over-represented in the cutaneous microbiota of hospitalised patients, and *Pseudomonas aeruginosa* is both a frequent coloniser of disrupted skin and an occasional significant cutaneous pathogen.

Streptococcus pyogenes (Group A beta-haemolytic *Streptococcus* [GABHS]), is a critical and perhaps the most frequent pathogen isolated from all severe SSTI, particularly in the absence of inoculating trauma, either in pure culture or cocultured with other pathogens. GABHS is a frequent cutaneous commensal infection often initiated via apparently superficial or relatively minor regions of inflammatory or fungal dermatoses. Its most frequent severe manifestations are erysipelas and necrotising fasciitis. *S. aureus* is a frequent post-traumatic pathogen, whether via injury or surgery. Contact with fresh, estuarine or marine water, particularly with associated trauma predisposes to infection by *Vibrio cholerae* and the Halophilic *Vibrionaceae* . In addition to beta-haemolytic Streptococci, necrotising or gangrenous cellulitis may also include the anaerobic spore-forming gram-positive bacilli, *Clostridium* sp., especially *Clostridium perfringens* and *C. septicum* . Any of these pathogens may produce blistering cutaneous eruptions associated with rapidly progressive infection of multiple integumental layers and deeper structures, in association with severe sepsis syndromes. Other organisms associated with necrotising infections include *Bacteroides* sp, *Peptostreptococcus* sp, *E. coli* and *K. pneumoniae* . *P. aeruginosa* , either independently or often in tandem with *S. aureus* is a common cause of infected burns, trauma and cutaneous ulceration from other causes.

Pathogenesis

Microorganisms cause SSTIs if: (1) there is a break in the skin because of a traumatic lesion or maceration; (2) the soft tissues are ischaemic; (3) virulent bacteria are present, such as community-acquired methicillin-resistant *S. aureus* (CA-MRSA) [6] ; (4) there are surgical site infections [7] ; or (5) the patient is severely immunocompromised. [7,8] Skin lesions can on occasion be manifestations of systemic infection; examples are bacteraemia with Meningococci or endocarditis. In this chapter, we do not address secondary infections; fungal, parasitic or mycobacterial infections; dressings; surgical techniques; wound care; or the epidemiology and prevention of healthcare-associated SSTIs.

Some strains of beta-haemolytic Streptococci and Staphylococci may produce the severe illness of toxic shock syndrome (TSS) through the production of T-cell superantigen exotoxins; the most well-known are the staphylococcal TSST-1 and enterotoxin B. Patients with TSS may present with widespread erythroderma, hypotension, acute kidney injury, desquamation at the digital extremities and thrombocytopenia and may initially resemble a severe SSTI. Most staphylococcal TSST-1-associated cases relate to menstrual tampon use, but Staphylococcal cutaneous wound infections can occasionally be associated with this illness. In contrast, Streptococcal TSST production is almost always associated with necrotising fasciitis (NF). *S. pyogenes* contains numerous virulence factors thought to be important in the pathophysiology of NF including the M-protein (especially types 1-2), a hyaluronic acid capsule, adherence to vimentin and pyrogenic exotoxins. M-protein, hyaluronic acid capsule and an S-protein allow the bacteria to evade host innate immune responses by coating the cell in host protein, particularly fibrinogen and erythrocyte membranes. Streptococcal pyrogenic exotoxin B (SpeB) has very broad enzymatic specificity allowing the enzyme to cleave numerous host immune effector molecules and intercellular barrier molecules at epithelial cell junctions.

Epidemiology

SSTIs are a diverse group of clinical syndromes that have varying severity and are associated with a wide range of pathogens. There has been a steady increase in the incidence of SSTIs [9], [10] and rates of emergency department visits increased between 2000 and 2010, from 6.4 to 13.5 per 1000 persons. [11] Also, SSTIs frequently cause sepsis and can be responsible for 6.5% of cases of septic shock. [12] The burden of SSTIs was shown in a European study where adult patients had a median length of hospital stay of 12 days; 6.5% required admission to the ICU, and 37% required surgical intervention.[13] NF and necrotising myositis are the most feared SSTIs that can affect even the healthiest young individual with very rapid onset and rapid progression to death.[9–11] Mortality rates historically range between 20% and 30%.[12–16] More recently, a study of death certificates showed a crude mortality rate of 4.8 deaths/1,000,000 person-years, with no significant time trend in the number of fatal NF during the study period.[17] Another study showed that, despite increasing co-morbidities, there has been a decrease in mortality from 9.0% to 4.9%.[18]

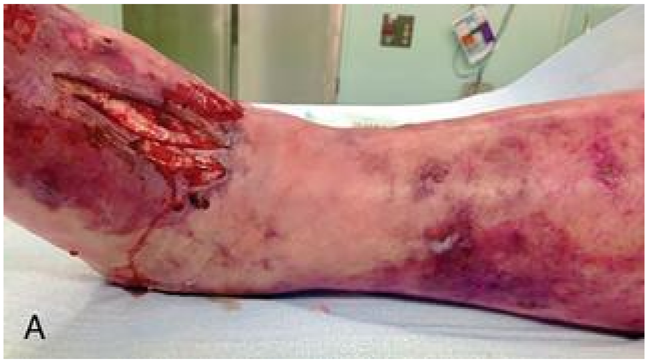
Risk factors predisposing to severe infection are important issues when taking a history from a patient with a suspected necrotising skin and soft-tissue infection (NSSTI). Lymphoedema, whether it be primary, consequential to lymphadenectomy, or any other cause of lymphatic obstruction (e.g. abdominal obesity), needs to be identified as management of this is important for successful therapy of the index episode and also prevention of recurrence.[14, 15] Lymphoedema is a particular risk factor for GABHS infection and erysipelas. Severe soft-tissue trauma with retained foreign material and devitalised tissue represents an urgent surgical management problem and predisposes to Clostridial infection. Tissue ischaemia, due either to arterial or venous insufficiency requires correction early in the management of associated infection. Systemic immunosuppression either for treatment of malignancy, connective tissue diseases or transplantation has broadened the range of opportunistic severe skin pathogens to include such organisms as *Aspergillus sp* . and the agents of cutaneous mucormycosis. Travel to endemic areas, particularly with contact with infected animals or animal products is important, particularly for patients with necrotising chancriform lesions such as that due to cutaneous anthrax (*B. anthracis* infection). The proportion of NSSTI attributable to gram-negative bacilli is reportedly increasing, particularly amongst immunosuppressed and frail patients residing in long-term care facilities, and those with recent antibiotic therapy for other infections.[16]

Clinical Presentation

NSSTI typically involves the lower limbs most frequently, followed by the external genitalia and less frequently other anatomical locations.[17] Pain, fever, erythema/warmth, tenderness and induration are early symptoms and signs. Purple discolouration, haemorrhagic bullae, surgical emphysema, shock and organ failure occur later. Cutaneous manifestation may even be absent at initial presentation, a significant contributor to an initial misdiagnosis rate of up to 70%.[17]

The terms cellulitis and erysipelas are anatomical diagnoses, both are typically due to beta-haemolytic streptococcal infection. Erysipelas typically involves the superficial dermis and characteristically has a distinct ridge at the margins of the acutely inflamed and erythematous infected tissue, whereas the margins of cellulitis are more indistinct, and infection extends to the deep dermis and subcutaneous tissues. Both may be in association with bacteraemia. Dermal oedema results from the prominent lymphatic blockade associated with erysipelas. It is sometimes difficult to discriminate between the two entities on clinical grounds alone. Ultrasound may be helpful in protracted cases to exclude underlying abscesses or if there are concerns about the presence of a deep venous thrombosis.

NF presents as a rapidly progressive erysipelas/cellulitis, that typically has pain disproportionate to clinical signs, and is associated with progressive necrosis and liquefaction of surrounding tissues, and the sepsis syndrome (Fig. 22.1). Penetrating trauma, crepitations of surgical emphysema and fever can be present but are not essential for the diagnosis. Bullae may form but discharge of purulent material does not. Lesions may become pain free due to infarction of regional nerves by microthrombi. There may also be ‘skip lesions’ whereby areas of skin necrosis are separated by normal-appearing skin; this is probably a result of separate cutaneous perforator thrombosis as the infection spreads along the deep fascial plane.



The photos show necrotizing fasciitis of the left lower limb. Photo A displays the lateral view of the foot and leg with haemorrhagic, darkened skin patches interspersed with relatively normal skin in a skip lesion pattern. An incision exposes underlying tissue necrosis. Photo B shows the medial ankle with severe cutaneous blistering and extensive necrosis. The skin surface is irregular with haemorrhage, and the soft tissues appear severely damaged.

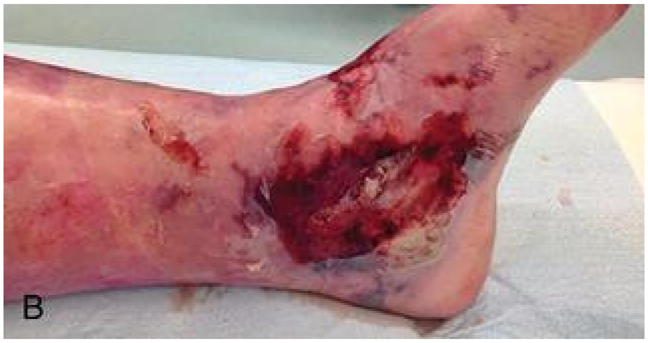


FIG. 22.1 Necrotising fasciitis of the left lower limb. (A) Haemorrhagic appearance of the skin on the foot and leg with relatively normal skin in between – skip lesions. An incision has been made to reveal underlying tissue necrosis and ‘dirty dishwater’ fluid leaking from the wound. (B) Medial view of ankle showing cutaneous blistering and necrosis.

Fournier’s gangrene is essentially NF of the external genitalia and perineum and may be preceded by a more indolent genital cellulitis or perianal abscess. [18] The majority of patients are aged 50 to 79 and the male–female ratio is 10:1, with an overall incidence of 1.6/100,000. [18] Risk factors include diabetes mellitus, alcoholism, urogenital trauma and urological interventions, chronic kidney disease, malignancy and HIV infection. [18] The receipt of notifications of Fournier’s gangrene cases in patients taking sodium-glucose cotransporter-2 (SGLT-2) inhibitors for diabetes by the U.S. Food and Drug Administration (FDA) Adverse Event Reporting System (FAERS) prompted a safety review and alert. [19] The U.S. FDA identified 12 cases of Fournier’s gangrene from 2013 to 2018 in Americans between 2013 and February 2018. [19] Further work is required to confirm a causal association; however, recent studies suggest there may at least be a consistent association between the use of this group of glycosuric drugs and Fournier’s gangrene. [20] The basic principles of the critical care, medical and surgical management of this urological emergency are the same as for other NSSTIs.

Because of the difficulties in initial diagnosis, many attempts at scoring systems have been made to improve diagnostic accuracy. One such scoring system is the Laboratory Risk Indicator for NECrotising fasciitis (LRINEC) [21] (Table 22.1).

Table 22.1

LRINEC scoring system for necrotising fasciitis

PARAMETER	RANGE	SCORE
Hb (g/L)	>135	0
	110–135	1
	<110	2
Leucocytes (10^9/L)	<15	0
	15–25	1
	>25	2
Sodium (mmol/L)	<135	2
Creatinine (µmol/L)	>141	2
Glucose (mmol/L)	>10.0	1
C-reactive protein	>150	4

Score: ≤5 = <50% risk (low); 6–7 = Intermediate risk; ≥8 = >75% risk (high).

Diagnosis

It cannot be over-emphasised that a prompt, correct clinical diagnosis of an NSSTI is absolutely critical for the survival of that patient and their safe and effective treatment.[22, 23] The provisional diagnosis, which can be difficult, is essentially a clinical one based on the presentation (e.g. rapid-onset redness and profound pain that spreads over time, which may be accompanied by fever, shivering or hypotension; or the presence of an abscess with pus). In the initial stages of the disease, SSTIs may be confused with either simple cellulitis, a subcutaneous abscess or sometimes, a musculoskeletal injury. Clinical signs and symptoms may change rapidly. A time course of NSSTI is summarised in Table 22.2 .

Table 22.2

Signs and symptoms associated with NSSTI – by time course

EARLY	LATE	VERY LATE
Fever	Violaceous discolouration	Visible necrosis
Pain	Haemorrhagic bullae	Dishwasher pus
Tenderness	Crepitus/surgical emphysema	Hypoaesthesia
Erythema/warmth	Hypotension	
Induration	Organ dysfunction	

Adapted from Peetermans M, de Prost N, Eckmann C, Norrby-Teglund A, Skrede S, De Waele JJ. Necrotizing skin and soft-tissue infections in the intensive care unit. Clin Microbiol Infect. 2020;26(1):8-17. doi:10.1016/j.cmi.2019.06.031

For a suspected deep-seated infection, imaging modalities need to be selected carefully with emphasis on rapid execution, rapid reporting and clinical liaison between radiologist and clinician. NF is mostly a clinical diagnosis and prompt surgical treatment should not be delayed by imaging in patients with characteristic presentations. [24] Computed tomography (CT) scanning may be helpful in equivocal cases, with a diagnostic sensitivity of 88.5% and sensitivity of 93% for the detection of NF. [24] Other features of NF on CT scan include thickening of the superficial and deep fascia, inflammation and fluid extending along facial planes into intermuscular septa and muscles and the non-enhancement of fascia. Ultrasound is of limited sensitivity in NF cases. [24] While MRI may provide superior tissue contrast sensitivity, CT scan is usually the preferred cross-sectional imaging modality in these acute situations because of more widespread availability and speed of image acquisition.

An attempt at the collection of definitive microbiological samples is essential upon presentation to medical attention, despite results not becoming available until after initial empirical medical therapy and surgical treatment have taken place. A minimum of two sets of blood cultures (aerobic and anaerobic specimens) should be collected at initial presentation along with swabs from wounds or ulcers with clinical features of infection, or aspirates of pus or blister fluid. This can typically be achieved during the initial emergency room assessment before the administration of empiric antibiotics. Operative tissue and pus specimens for culture and histopathology are also essential to guide definitive antimicrobial therapy, and to also aid in determining the significance of organisms that may not typically associate with NSSTI (Table 22.3). Tissue and fluid specimens from (normally) sterile sites are preferred. Growth of microorganisms *per se* from swab specimens may not be pathognomonic of infection since some differential diagnoses of SSTIs (e.g. primary ischaemic necrosis, allergy, pyoderma gangrenosum, venous thrombosis or stasis dermatitis) may be associated with a breach of the cutaneous barrier and consequent opportunistic residential bacterial flora. [25] Liaison between the managing clinician and the medical microbiology or infectious diseases services can assist in resolving clinical diagnostic and management dilemmas in these cases. Serology is only useful for the retrospective diagnosis of some Group A, C and G beta-haemolytic streptococcal infections and has no role in the context of NSSTI diagnosis.

Initial Management

The mainstays of the management of a patient with NSSTI are surgical debridement, antimicrobial therapy, fluid and electrolyte replacement and end-organ support. The emergency assessment of a patient with suspected NSSTI must be both prompt and thorough, paying attention to the detailed mechanism of any injury and the severity of the patient's sepsis syndrome. Occasional patients may present with atypical features such as 'the worst pain I have ever had' in association with a fever. Those presenting with pain disproportionate to clinical examination findings are particularly challenging, particularly in the context of an emergency department. Table

22.3 lists some clinical features and associated potential NSSTI pathogens or disease entities the attending clinician should consider.

Table 22.3

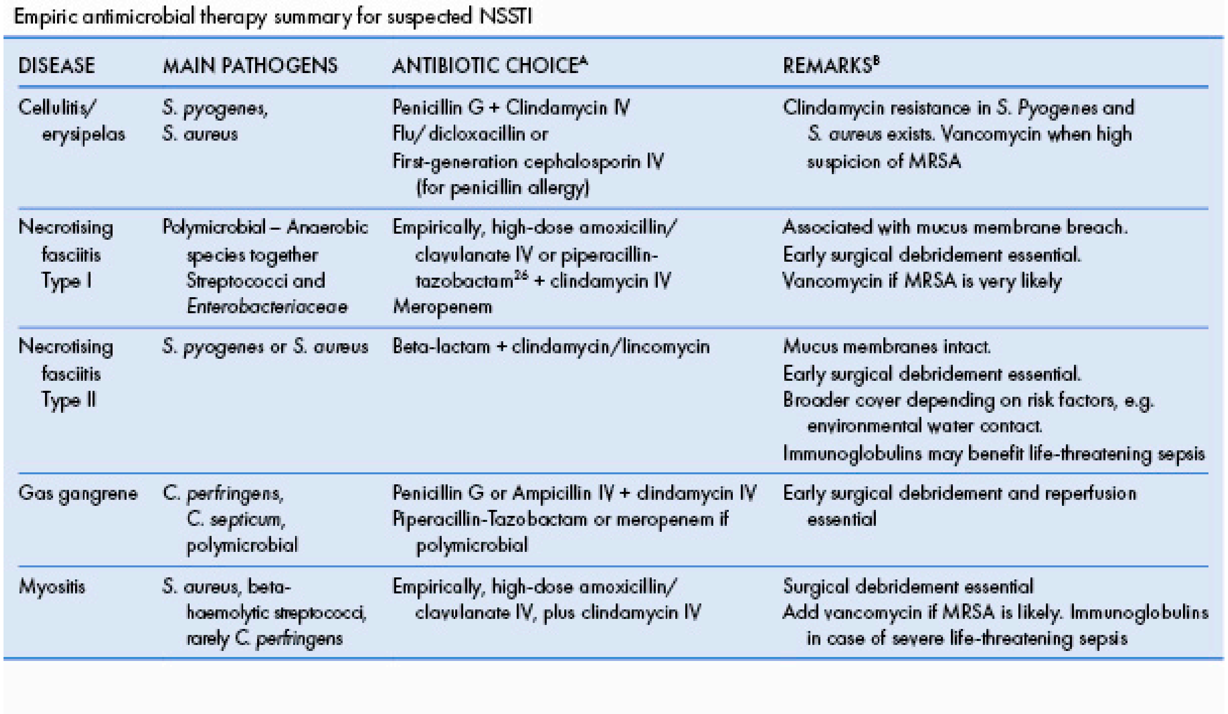
Clinical triggers and associated potential NSSTI entities or pathogens

CLINICAL TRIGGER	DISEASE/PATHOGEN
SGLT2 agonist, diabetes	Fournier's gangrene
'Worst pain I have ever had'	*S. pyogenes* , *Clostridium sp.*
Prominent edge to erythema	*S. pyogenes* – erysipelas
Marine/estuarine water contact	Halophilic Vibrionaceae – e.g. *V. vulnificus*
Bite (cat or dog)	*Pasteurella multocida*
Iron overload	Vibrionaceae
Road/battlefield trauma	*Clostridium sp., Bacillus sp* ., polymicrobial
Neuropathic ulceration	Polymicrobial
Burns	*P. aeruginosa*
Environmental water contact	*Aeromonas sp.*
Soil from tropical regions	*Burkholderia pseudomallei*

The efficient collection of definitive diagnostic microbiological specimens should be achieved during this initial assessment. At present, whilst an interesting development in diagnostic pathology, the role of rapid microbiological diagnostic testing (e.g. rapid PCR detection methods for sepsis-associated pathogen DNA in blood culture specimens) in the management of NSSTIs remains uncertain, [27] particularly challenging for this technology is the polymicrobial nature of many of these infections.

There is growing evidence that empiric antibiotic therapy (Table 22.4) should commence within an hour of arrival at an emergency department or after recognition if already an inpatient. [28-31]

Table 22.4



Empiric antimicrobial therapy summary for suspected NSSTI

DISEASE	MAIN PATHOGENS	ANTIBIOTIC CHOICE[A]	REMARKS[B]
Cellulitis/ erysipelas	*S. pyogenes*, *S. aureus*	Penicillin G + Clindamycin IV Flu/ dicloxacillin or First-generation cephalosporin IV (for penicillin allergy)	Clindamycin resistance in *S. Pyogenes* and *S. aureus* exists. Vancomycin when high suspicion of MRSA
Necrotising fasciitis Type I	Polymicrobial – Anaerobic species together Streptococci and *Enterobacteriaceae*	Empirically, high-dose amoxicillin/ clavulanate IV or piperacillin-tazobactam[26] + clindamycin IV Meropenem	Associated with mucus membrane breach. Early surgical debridement essential. Vancomycin if MRSA is very likely
Necrotising fasciitis Type II	*S. pyogenes* or *S. aureus*	Beta-lactam + clindamycin/lincomycin	Mucus membranes intact. Early surgical debridement essential. Broader cover depending on risk factors, e.g. environmental water contact. Immunoglobulins may benefit life-threatening sepsis
Gas gangrene	*C. perfringens*, *C. septicum*, polymicrobial	Penicillin G or Ampicillin IV + clindamycin IV Piperacillin-Tazobactam or meropenem if polymicrobial	Early surgical debridement and reperfusion essential
Myositis	*S. aureus*, beta-haemolytic streptococci, rarely *C. perfringens*	Empirically, high-dose amoxicillin/ clavulanate IV, plus clindamycin IV	Surgical debridement essential Add vancomycin if MRSA is likely. Immunoglobulins in case of severe life-threatening sepsis

[a] Once causative pathogens have been identified, antibiotic choice can be modified, and its spectrum narrowed.

[b] Be aware of local endemicity of community- or hospital-acquired MRSA. Co-trimoxazole or clindamycin is the choice in most community-acquired low-grade infections; for all other cases, vancomycin is used.

IV , Intravenous; *MRSA* , methicillin-resistant *S. aureus*

Assessment of fluid and electrolyte status is essential with prompt fluid resuscitation consistent with clinical need and ongoing close observation. Early referral to an ICU is an important consideration.

Surgical Management

Timely surgical debridement is the mainstay of treatment and good source control improves morbidity and mortality. [32] Access to an operating theatre within 12 hours is associated with lower mortality. [33] Sharp excision of the infected skin and subcutaneous tissue is performed under general anaesthesia. All necrotic and non-viable tissue is removed, and the margins of excision will depend on the extent of the erythema and underlying fasciitis if present. In a very unwell patient who is receiving inotropic support, the excision should be aggressive enough to go a little beyond the margins of erythema to normal healthy skin. Often it will be necessary to carry the excision all the way down to deep fascia, and sometimes include the deep fascia which will often expose bone and periosteum, tendons, intermuscular septae and retinaculae. Importantly, limb amputation is very rarely needed and is only indicated if there is associated myositis and myonecrosis and in this situation, amputation may be lifesaving.

The skin edges should bleed, and the subcutaneous fat should be a healthy yellow colour at the end of the procedure. Another clue that the debridement is adequate is the improvement in haemodynamics (i.e. a reduction in the need for inotropic support). Certainly, when the patient returns to the ICU, a downtrend in inotropic support is a good indication that source control is adequate.

Operative tissue and fluid specimens should be sent for microbiological analysis. The wounds should be dressed to allow for an early return to theatre (within 24–48 hours) and further debridement as necessary. Reconstruction of the skin defect is planned early and mainly consists of autologous split skin grafting. Free tissue transfer is rarely indicated. Limb amputation is usually a last resort but is sometimes necessary for definitive wound closure and to avoid prolonged hospitalisation and the associated morbidity which follows.

Medical management

Close liaison between all attending clinicians and the microbiology laboratory is in the patient’s best interests. Empiric antibiotic management needs to be cognisant of the mechanism of injury, relevant risk factors and their treatment (e.g. diabetes, neutropenia from cytotoxic chemotherapy and arterial ischaemia) and of the actual or likely pathogen(s) and local antibiotic resistance patterns. This includes understanding if the infection is community-acquired or healthcare-associated, and the local prevalence of multi-resistant organisms such as non–multi-resistant MRSA, extended-spectrum beta-lactamase- or carbapenemase-producing *Enterobacterales* , and resistant *P. aeruginosa.* Mixed infection can occur in up to 25% of NSSTI, [16] which needs to be anticipated by the treating clinician, as underappreciation of this can result in inappropriate treatment rates of up to 40%. [16]

Microbiological culture results need to be reviewed daily to facilitate prompt de-escalation of broad-spectrum empiric therapies to narrower-spectrum antibiotics. Many of the definitive pathogens described in this chapter are susceptible to narrower-spectrum agents. However, as with other infections, multi–drug-resistant gram-negative bacilli such as carbapenemase-producing *Enterobacterales* (CRE), *P. aeruginosa* (CRPA) and the *Acinetobacter baumannii* complex (CRAB) and *Stenotrophomonas maltophilia* can be occasional NSSTI co-pathogens. [34-36] This reinforces the requirement for the managing clinicians to liaise closely with the microbiologists and minimise delays in optimising therapy.

Most recognised treatment guidelines recommend a combination of an IV betalactam-betalactamase inhibitor (e.g. amoxicillin-clavulanate or piperacillin-tazobactam) plus clindamycin; with the addition of vancomycin if there are clinical concerns about non–multi-resistant MRSA or if the NSSTI relates to device implantation. For NSSTI arising in association with either a mucus membrane breach or penetrating trauma, adequate coverage against Enterobacterales with an aminoglycoside is important. A carbapenem or ceftazidime should be included if the NSSTI is arising from trauma acquired in a tropical environment to cover cutaneous melioidosis. Wounds with environmental water contamination that develop NSSTI may contain *Aeromonas sp* ., which can produce beta-lactamases and carbapenemases and therefore ciprofloxacin should be added in those cases. Microbiological culture guidance is essential for antibiotic treatment of multi-resistant organisms. While clinical trials are lacking for NSSTIs, some data gathered from clinical trials of newer agents that have included complicated SSTI patients suggest that ceftazidime-avibactam, ceftolozane-tazobactam, cefiderocol, delafloxacin, finafloxacin and murepavadin may be acceptable agents for NSSTI that are due to multi-resistant GNBs.[35] For NSSTI due to multi-resistant gram-positive pathogens (e.g. MRSA), ceftaroline, tigecycline, daptomycin and linezolid have emerging therapeutic roles; again as part of culture-directed approach with appropriate antimicrobial stewardship.[25]

The addition of clindamycin to beta-lactam therapy for invasive beta-haemolytic Streptococcal infection is important. Clindamycin inhibits Streptococcal growth during its stationary phase and inhibits the production of many Streptococcal exotoxins and virulence factors. This was initially demonstrated in in vitro and experimental animal models. Recent human studies have demonstrated an approximate 50% mortality reduction[37] when clindamycin is added to Beta-lactam therapy of severe, invasive Beta-haemolytic Streptococcal infections, independent of the presence of either shock or NF. Importantly, this mortality advantage does not apply to patients with invasive non–beta-haemolytic Streptococcal infection.[37]

The duration of antibiotic therapy remains uncertain and not settled by clinical trials. Most guidelines advocate that intravenous antibiotics can be switched to oral therapy once there has been an appreciable clinical improvement, the patient has been afebrile for 48 to 72 hours and important predisposing surgical factors have been treated (e.g. abscess drained, limb re-perfused, foreign and dead tissue debrided). Oral antibiotics can be ceased when the clinician determines the infection has resolved but it is not essential for all wounds to be healed.

Adjuvant therapies, including intravenous immunoglobulin (IVIG) preparations and hyperbaric oxygen therapy (HBOT), have been advocated for NSSTI. HBOT is expensive, time-consuming and not risk-free but can be performed safely for critically ill patients in experienced centres. A Cochrane review in 2018 failed to identify prospective clinical trials supporting its use.[38] Recent publications have not convincingly demonstrated any attributable benefit to the addition of HBOT in the management of NSSTI in ICU patients.[17,32,39] At this point, it is difficult to recommend its use in the absence of positive evidence from robust clinical trials. HBOT should not delay debridement and antibiotic therapy.[40,41]

IVIG has been postulated as adjuvant NSSTI therapy. Theoretically, IVIG may neutralise the microbial toxins emanating from the infection that causes harm and have immunomodulatory functions, facilitating bacterial opsonisation. [17] However, limited use in NSSTI has restricted empirical analysis. A propensity score-matched analysis study from 130 American hospitals demonstrated that IVIG was used infrequently in NSSTI patients and had no discernable impact on mortality or duration of hospital stay beyond that conferred by surgical debridement and antibiotic therapy. [38] A recent Swiss retrospective cohort study of 48 patients (22 treated with IVIG) again concluded that there was no clear evidence to support the addition of IVIG to debridement, antibiotics and supportive care. [42]

Summary

The correct initial diagnosis of an NSSTI is both vital and fraught with difficulty. Clinical suspicion for this entity must remain high and a patient may require multiple reviews by the same observer to make a diagnosis. The diagnosis is typically a clinical one with supportive laboratory and radiological evidence. Timely collection of definitive microbiological specimens, the institution of antibiotics and fluid resuscitation/supportive care and emergency surgical debridement are the pillars of successful treatment. While broad-spectrum antibiotics are recommended at the commencement of therapy, close liaison between the attending surgeons, physicians and medical microbiologists ensures that optimal definite therapy can proceed in a timely manner. The most important pathogens include GABHS and *C. perfringens* , which typically remain susceptible to narrow-spectrum antibiotics.

Overview of shock

Matthew J. Maiden, Emily J. See and Sandra L. Peake

Definition

Shock is a fundamental disease state of critical illness. However, many clinicians who manage shocked patients remain vague about what the definition of shock is. A commonly offered description is ‘a patient with a low blood pressure’, followed by some threshold blood pressure below which ‘shock’ is said to be occurring.

Uncertainty about this important concept may be because the term ‘shock’ is used in a multitude of contexts – septic, haemorrhagic, distributive, hypovolaemic, cytotoxic, cardiogenic, anaphylactic, toxic, spinal, neurogenic, cervical, electrical and even emotional shock. Regardless, the unifying feature of shock irrespective of the initiating disease or clinical features is **acute circulatory failure associated with inadequate oxygen utilisation by the cells.** [1]

A thorough understanding of what constitutes shock is essential for all critical care practitioners. This chapter will outline the pathophysiology of shock, a classification of diseases that lead to shock and an approach to management.

Circulatory Physiology

Oxygen delivery

Supply of oxygen to the cells is tightly regulated by the cardiovascular system. Oxygen delivery (DO_2) is the product of cardiac output (CO) and the oxygen content of arterial blood. DO_2 (mL/min) can be summarised by the following equation:

$$\mathbf{DO_2 = CO \times ([1.34 \times Hb \times SaO_2] + [PaO_2 \times 0.003])}$$

where Hb is the haemoglobin concentration (g/L), SaO_2 is the arterial haemoglobin (Hb) oxygen saturation and PaO_2 is the arterial oxygen partial pressure in mm Hg. The exact value of the haemoglobin O_2-carrying capacity constant is variably listed as either 1.34 mL O_2/g Hb (directly measured) or 1.39 mL O_2/g Hb (theoretical maximum O_2 carrying capacity).

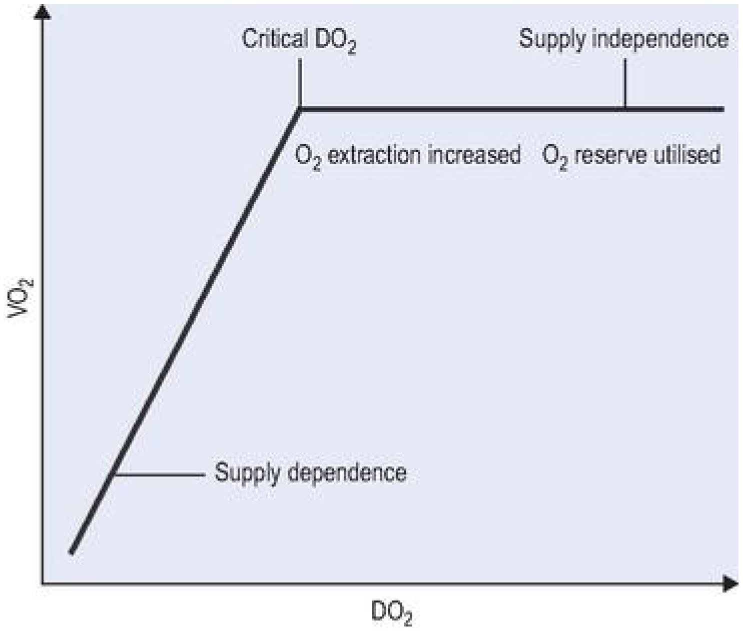
Assuming adequate arterial oxygen content, cardiac output is the main determinant of DO_2. Cardiac output is the product of heart rate (HR) and stroke volume (SV). Stroke volume is influenced by preload, afterload and myocardial contractility. Thus:

$$\mathbf{CO = HR \times SV\ (preload, afterload, contractility)}$$

Alterations in any of these determinants of cardiac output will eventually lead to the development of different ‘types’ of circulatory shock (e.g. hypovolaemic, distributive and cardiogenic).

DO_2–VO_2 relationship

DO_2 in adults at rest is approximately 1000 mL/min, while oxygen consumption (VO_2) is about 250 mL/min. Under normal circumstances, the ‘extra’ oxygen being supplied is not required to meet metabolic demand and can conceptually be thought of as a ‘reserve’ supply (O_2 supply independency). If DO_2 decreases, VO_2 initially remains unchanged as the ‘reserve’ oxygen is utilised. If DO_2 falls further, oxygen extraction from Hb is increased to maintain adequate oxygen supply to the tissues. Any further reduction of DO_2 results in oxygen being maximally extracted from Hb. At this point, VO_2 becomes dependent on DO_2 (O_2 supply dependency) and energy production in cells is limited by the supply of oxygen to tissues (Fig. 23.1). This relationship has been illustrated in animal models of haemorrhagic shock and may be more complex in humans with different acute and chronic diseases.



The graph presents V O 2 on the vertical axis and D O 2 on the horizontal axis. The plotted curve begins with a rising linear segment followed by a horizontal plateau. The initial rising segment is labelled supply dependence, representing a phase where V O 2 increases in proportion to D O 2. The transition point between the rising and plateau segments is labelled critical D O 2. The horizontal segment is annotated with the phrases O 2 extraction increased and O 2 reserve utilised, followed by supply independence further along the axis. The chart conceptually divides oxygen consumption into a phase dependent on supply and another phase where oxygen extraction compensates to maintain constant V O 2 beyond a critical threshold.

FIG. 23.1 Oxygen supply and demand relationship.

Dysoxia

Dysoxia is the cellular response to inadequate oxygen delivery. It occurs beyond the critical point of oxygen supply dependency (critical DO_2). Inadequate oxygen supply leads to anaerobic cellular metabolism, less efficient glycolytic adenosine triphosphate (ATP) production and consequent cellular and organ dysfunction. If the process leading to shock is identified and managed early, cellular dysfunction may be limited. However, if shock persists, the ongoing limitation of oxygen supply affects cell membrane ion channels, leading to an influx of sodium and water, cellular oedema, breaching of cell membrane integrity, cell injury and eventually cell death.

The ability to withstand limited oxygen supply varies between organs. The heart and brain have high metabolic requirements with a relatively high oxygen extraction, and hence, are more vulnerable to reduced oxygen supply. In contrast, the kidney and skin have relatively lower metabolic requirements and lower oxygen extraction so are more tolerant of decreased DO_2. The critical DO_2 also varies between individuals and is affected by metabolic demand, age, disease states and medications.

Dysoxia may also occur despite adequate DO_2. In conditions such as sepsis and multi-organ dysfunction syndrome, DO_2 can appear to be adequate (and may even be supra-normal as a result of increased CO). However, arteriolar shunting around the micro-vascular capillary beds prevents adequate oxygen delivery to the cells, and inflammatory mediators can induce mitochondrial dysfunction impairing cellular utilisation of available oxygen.[2-4] Hence **hypotension is not required to define ‘shock’.**

Shock Syndromes

Shock is commonly classified according to the component of the circulation that is primarily disturbed. For example,

- hypovolaemic shock – inadequate preload
- cardiogenic shock – pump failure

- distributive or vasodilatory shock – altered vascular capacitance

Although this distinction is sometimes too simplistic, the classification of shock in this way is clinically useful as it has therapeutic implications. For example, in septic shock, hypovolaemia, vasodilation and myocardial dysfunction may all co-exist.

Hypovolaemic Shock

Total blood volume is 70 mL/kg and comprises blood cells and plasma. Hypovolaemic shock occurs when acute loss of blood or fluid leads to decreased circulating blood volume (Box 23.1).

Box 23.1

Causes of hypovolaemic shock

Blood loss

Vascular injury (e.g. trauma and surgery)
Gastrointestinal bleeding (e.g. peptic ulcer, diverticulae angiodysplasia and varices)
Obstetric bleeding (e.g. placenta praevia and post-partum haemorrhage)
Intra-abdominal haemorrhage (e.g. splenic laceration and liver injury)
Retroperitoneal (e.g. aortic aneurysm, ectopic rupture, femoral artery bleeding and pelvic fracture)
Long bone fracture
Pulmonary haemorrhage, haemothorax

Fluid loss

Vomiting
Diarrhoea
Ileostomy losses

Sweating
Polyuria (e.g. diuretics, glucosuria and diabetes insipidus)
Burns
Pancreatitis
Ascites

Inadequate fluid intake

Loss of circulatory volume decreases preload and stroke volume. About 10% of circulating volume loss can be restored by the movement of interstitial fluid into the circulation. Blood loss beyond this invokes cardiovascular compensatory mechanisms to restore preload and maintain CO and systemic blood pressure. These mechanisms include:

1. Increasing venous tone. Venoconstriction is an early compensatory response to hypovolaemic shock. The venous system holds about 80% of the total blood volume and acts as a blood reservoir. The sympathetic nervous system controls venous tone and capacitance. Reducing capacitance favours venous return to the heart in an attempt to maintain stroke volume.
2. Increasing arteriolar tone. Sympathetic stimulation of arteriolar resistance vessels increases perfusion pressure to the organs. However, this does not necessarily equate to increased organ blood flow. The extent of change in arteriolar tone varies to redistribute blood flow to the vital organs.
3. Increasing heart rate. To compensate for the reduction in stroke volume, heart rate is increased to maintain cardiac output.
4. Increasing contractility. The heart will contract more vigorously to increase stroke volume and maintain cardiac output. A diseased heart may not be able to adequately increase contractility, which further compounds shock.

Priorities in the management of hypovolaemic shock are to (1) control the source of blood and/or fluid loss, and (2) restore the circulating volume.

Cardiogenic Shock

The heart is central to maintaining adequate delivery of oxygen to tissues. If the pump fails, few compensatory mechanisms are available, which contributes to the high mortality risk of cardiogenic shock (~45%–100% depending on the aetiology).[5] Myocardial ischaemia is the most common cause of cardiogenic shock, but other aetiologies must be considered (Box 23.2).

Box 23.2

Causes of cardiogenic shock

Myocardial ischaemia
Acute valve dysfunction (e.g. chordae rupture and prosthetic valve thrombus)
Myocarditis
Myocardial contusion
Septal/ventricular rupture
Cardiomyopathy
Drugs (e.g. Ca^{2+} channel-blocker overdose and β-blocker overdose)
Extrinsic compression (e.g. tension pneumothorax and tamponade)
Pulmonary emboli, pulmonary hypertension
Bradyarrhythmias (e.g. complete heart block)
Tachyarrhythmias (e.g. atrial or ventricular tachycardias)

Treatment priorities in cardiogenic shock involve urgent correction of the underlying acute cardiac disease and consideration of afterload reduction while ensuring adequate organ perfusion.

Obstructive Shock

Mechanical obstruction to the flow of blood through the cardiac chambers will lead to reduced cardiac output. Limitation of flow may be due to:

- obstruction within the heart (e.g. valve thrombosis and myxoma)

- extrinsic compression (e.g. tension pneumothorax and cardiac tamponade)
- cardiac outflow obstruction (e.g. pulmonary embolus and hypertrophic obstructive cardiomyopathy).

Treatment is directed at urgent removal of the obstruction (e.g. drainage of pericardial effusion and lysis of thromboembolism).

Distributive Shock

Arteriolar autoregulation, the autonomic nervous system and vasoactive hormones control the distribution of blood around the vascular network. Distributive shock results from the failure of these mechanisms, leading to inappropriate distribution of blood (Box 23.3). Unlike other forms of shock, cardiac output may initially be increased as the heart endeavours to compensate for the maldistribution of blood.

Box 23.3

Causes of distributive shock

Septic shock
Toxic shock
Anaphylactic shock
Neurogenic shock
Adrenal/thyroid insufficiency
Toxicity (e.g. drugs)
As a component of multi-organ dysfunction syndrome

Management priorities include the identification and treatment of the precipitating cause and the optimisation of organ perfusion with resuscitation fluids and medications that support an appropriate cardiovascular response.

Clinical signs

Clinical features of shock reflect an inadequate circulation and insufficient oxygen delivery and/or utilisation.

Hypotension is a common feature of shock and often signifies circulatory failure. However, hypotension develops late as blood pressure is initially maintained by compensatory mechanisms (i.e. vascular constriction, tachycardia and increased myocardial contractility). A decline in mean arterial pressure (MAP) below the lower limit of autoregulation results in reduced perfusion to the vital organs. In a healthy adult, tissue perfusion is typically impaired when MAP falls below 50 mm Hg. However, elderly patients and those with pre-existing hypertension or vascular disease generally require a higher MAP to represent adequate regional blood flow.

Tachycardia is an early compensatory sign of shock, except in conditions where bradycardia is the cause of shock (e.g. complete heart block, increased vagal tone in cervical shock and unopposed vagal tone in neurogenic shock).

Tachypnoea increases with worsening shock but falls in the pre-terminal phase of shock.

Oliguria occurs secondary to reduced glomerular filtration rate. The rate of urine production may be a useful guide to assessing the adequacy of the circulation.

Altered mental status is a common feature of shock since cerebral function is very sensitive to altered oxygen delivery. Mental state progressively changes from anxiety, agitation, confusion and delirium, toward drowsiness and coma.

Impaired peripheral perfusion provides a clinically useful clue regarding the likely mechanism of shock. Cool, clammy peripheries with pale or mottled skin are suggestive of hypovolaemic or cardiogenic shock, whereas warm peripheries are suggestive of distributive shock.

It is important to recognise that clinical features of shock are non-specific and will differ depending on the type of shock, severity of precipitating disease, physiological reserve of the patient and effects of medications. For example, patients on β-antagonists will not mount the same tachycardic response as other patients, while patients with pre-existing cardiac disease are less capable of circulatory compensation and so develop features of shock earlier. Young patients typically have greater compensatory reserves and hence clinical signs of shock in this group of patients represent profound cardiovascular compromise. Due to the non-specific and varied clinical signs of shock, repeated assessment with frequent monitoring of vital signs is essential.

Management

Resuscitation of shock is a medical emergency. The aim of therapy is to rapidly and effectively restore systemic tissue perfusion and DO_2.[6] History, examination and investigation (Box 23.4) must occur concurrently with resuscitation. The usual 'ABC' resuscitation principles of airway, breathing and circulation apply.

Box 23.4

Investigations for shock (as clinically indicated)

Bedside

Arterial blood gas (including haemoglobin, lactate and SaO_2)
ECG
Ultrasound (e.g. FAST scan and AAA scan)
Echocardiogram

Laboratory

Full blood count, coagulation studies, D-dimer
Electrolytes, creatinine, urea, liver function tests
Cardiac enzymes, lipase
Cultures – urine, blood, sputum, pus
Toxicology assays

Radiology

Chest, abdominal X-ray
Trauma series radiology (chest, pelvis, C-spine)
CT scan

Angiography (e.g. coronary, visceral and pulmonary)

Ensure adequate oxygenation

Ensure adequate FiO$_2$ and SaO$_2$, that ventilation is not impaired, and that any reversible cause of pulmonary shunt is corrected (e.g. pleural collection and bronchus obstruction).

Vascular Access

Insertion of intravenous cannulae is essential for the administration of fluids and medications. Cannula size is an important consideration as it has major implications for the rate of laminar fluid flow. Poiseuille's law describes the variables contributing to laminar flow rates.

$$\mathbf{Q} \propto \left(\Delta \mathbf{P} \times \pi \mathbf{r}^4\right) / \left(\mathbf{8} \times \mathbf{viscosity} \times \mathbf{length}\right)$$

This emphasises the effect of radius and cannula length on flow. Hence for rapid intravenous fluid administration, venous cannulation using short, wide-bore catheters is advised.

Flow rates achieved through different diameter intravenous cannulae are stated to range from 44 mL/min (22 G; 0.9 mm diameter) to 286 ml/min (14 G; 2.1 mm diameter). However, flow through cannulae is turbulent rather than laminar and actual flow rates are lower than those quoted. [7]

A central venous cannula should be considered in patients with persistent shock, particularly if they are requiring infusion of catecholamines, other cardiovascular medications, multiple infusions or have difficult peripheral venous access. Whether vasoconstricting agents such as noradrenaline can safely be administered via a peripheral vein is currently being investigated (NCT03695445).

Fluid resuscitation

Fluid resuscitation is an important therapeutic strategy in the management of shock. [8] Although parenteral fluids are commonly used, there remain many questions regarding what 'dose' and type of fluid is best in shock. While hypovolaemia can contribute to states of shock, excessive administration of fluid increases the risk of hypervolaemia, its attendant adverse consequences and known association with mortality. [9] Resuscitation should therefore be titrated to clinical status and the haemodynamic response assessed before providing further fluid doses.

It is important to note that not all patients will respond to fluid loading with a significant increase in cardiac output. If the heart is working on the terminal (flat) portion of the Frank-Starling curve, increased preload may not significantly increase stroke volume. Furthermore, the relationship between pre-load and stroke volume is dynamic and affected by many other variables extrinsic to the heart (e.g. autonomic tone, cardiovascular medications, ventilation and lung disease). [10]

The likelihood of fluid responsiveness can be predicted using static variables (e.g. heart rate, blood pressure and CVP) or dynamic manoeuvres (e.g. passive leg raise, echocardiography and lung ultrasound). A passive leg raise test transiently increases venous return by 'auto-transfusion' of blood from leg and pelvic veins into the central veins which increases preload. Increases in cardiac output will be minimal if venous capacitance remains high and the extra blood volume can be accommodated. The haemodynamic response to passive leg raise can be used to assess whether fluid administration will enhance cardiac output. [11] However, a dynamic technique of cardiac output monitoring is required, and it may not be practical in patients with restricted positioning and mobility.

Crystalloid solutions

Crystalloid solutions comprise electrolytes (with or without dextrose) and water. These fluids cross semi-permeable membranes easily and are rapidly distributed throughout the intra-vascular and extra-vascular spaces. The time for fluid equilibration across compartments depends on (1) osmolality of the fluid; (2) solute clearance and; (3) integrity of the vascular endothelium.

Whilst the choice of fluid should reflect the composition of the fluid lost, 0.9% saline has traditionally been used for initial volume replacement. 0.9% saline is slightly hyper-osmolar (300 mOsm/L) and hyper-chloraemic (150 mEq/L) relative to plasma. When large volumes are used for resuscitation, hyperchloraemia can contribute to bicarbonate loss and a normal anion gap metabolic acidosis. For this reason, many clinicians advocate for the use of ‘balanced’ crystalloid solutions (e.g. Hartmann’s and Plasmalyte) as resuscitation fluid. Lactated Ringer’s solution (Hartmann’s) contains sodium, chloride, potassium, calcium and lactate (29 mEq/L), and is slightly hypotonic (254 mOsm/L) to plasma. However, the calcium in Hartmann’s (4 mEq/L) is incompatible with certain drugs and lactate levels may be elevated if hepatic function is markedly impaired, fluid administration is significant or if blood is sampled from an arm receiving intravenous fluids. Other crystalloid solutions are available that contain different buffer anions and slightly different compositions of electrolytes. Despite biochemical plausibility that balanced solutions would be preferable to 0.9% saline for fluid resuscitation, controlled clinical trials have revealed no difference in patient outcomes.[12, 13] However, meta-analysis using Frequentist and Bayesian analysis of 13 randomised controlled trials concluded there was a high probability that balanced solutions reduced mortality albeit with small size of effect and may not apply to all diseases.[14]

Concentrated saline is theoretically a useful resuscitation fluid since a small volume can increase circulating volume (e.g. 250 mL 7.5% saline can increase circulating volume by 500 mL). However, the sodium also passes into interstitial space leading to increased interstitial fluid volume, at the expense of intra-cellular volume.

Albumin solutions

4% normal serum albumin (NSA 40 g/L; 260 mOsm/L) is iso-oncotic and infusion rapidly increases circulating volume. Concentrated (20%) albumin is available in smaller volumes (100 mL). It increases circulating fluid volume by drawing fluid from the interstitium, and its use as a resuscitation fluid is currently being investigated.[15], [16]

In 1998, a Cochrane review suggested albumin use was associated with increased mortality,[17] but other reviews drew different conclusions.[18-20] To determine the safety of albumin as a resuscitation fluid, the Saline versus Albumin Fluid Evaluation (SAFE) study randomised 7000 patients to receive albumin or crystalloid as their resuscitation fluid.[21] This landmark study revealed that patients receiving albumin required less intravenous fluid, but clinical outcomes were no different to patients who received saline resuscitation. Sub-group analyses suggested that septic patients fared better with 4% NSA, while head-injured patients given saline had better outcomes.

Starch solutions

Starch solutions contain a carbohydrate polymer (starch) as their oncotic molecule and differ according to the type and molecular size of the starch used (high starch 450,000 D, medium starch 200,000 D, low starch 70,000 D). The starch polymers undergo degradation by serum amylase with the fragments cleared by the kidney. The duration of oncotic effect is related to the size of the starch molecule and clearance rates. While starch solutions provide effective intravascular volume replacement and are convenient to administer, their use in patients with septic shock has been associated with increased risk of death, renal impairment and bleeding risk.[22], [23]

Red blood cells

The use of blood is essentially limited to shock from acute blood loss or for correcting anaemia that may be contributing to impaired oxygen delivery.

Cardiovascular medications

When fluid administration alone fails to restore adequate oxygen delivery, consideration should be given to augmenting the circulation with medications that increase cardiac output and/or blood pressure. Terms such as inotropes, vasopressors, vasoactive agents and vasoconstrictors have been used to describe these medications. However, these terms have been used somewhat interchangeably and can lead to confusion about their mechanism of effect on the circulation. For these reasons, we have avoided their use in this chapter.

The choice of medication to use in shocked patients will depend on which aspect of the cardiovascular physiology is deranged and the therapeutic effect desired. For cardiogenic shock, medications may be required to increase contractility (e.g. dobutamine, adrenaline, milrinone and levosimendan), reduce afterload, maintain adequate systemic and coronary perfusion pressure, increase diastolic relaxation and increase (or decrease) heart rate. In distributive shock, medications are required to produce venoconstriction and arterial constriction to restore autoregulation of arterial flow. There is little role for cardiovascular medications in hypovolaemic shock although they may form part of a multimodal approach to resuscitation (Please see Chapter 26 for more information).

Catecholamines are the first-line medications used in shock. The choice of which catecholamine to use has been the subject of considerable debate and opinion. However, the superiority of one catecholamine over another has not been demonstrated in any large-scale clinical trials. A large randomised trial of patients with shock reported no difference in 28-day mortality between noradrenaline and dopamine [24] while an Australian trial found no difference between noradrenaline and adrenaline in patients with shock from any cause. [25] Similarly in septic shock, there is no mortality difference if using adrenaline alone, or noradrenaline with dobutamine. [26] A limitation of using adrenaline is its effect to increase glycolysis, glycogenolysis and lactate production, which can complicate interpretation of lactate levels during resuscitation.

Other vasoconstricting medications such as vasopressin are used when distributive shock and hypotension are resistant to catecholamines. Whilst vasopressin binds to V1 receptors leading to arterial vasoconstriction and increasing MAP, it has not provided survival benefits in distributive shock. [27] Similarly, hydrocortisone may be used as a catecholamine-sparing agent in shock, but in clinical trials has not contributed to improved survival. [28] Recently, synthetic angiotensin-2 has been trialled as an agent to increase MAP. This has been found to limit the need for noradrenaline, and further trials are underway to determine if angiotensin-2 administration provides a survival advantage in shock.[29], [30]

It is not surprising that there is no one ‘ideal’ cardiovascular medication given the wide range of conditions contributing to shock and the heterogeneity of patient factors. While distributive shock is the most common form of shock in an ICU,[6] we strongly caution against routine use of vasoconstricting agents for all hypotensive patients. Instead, the choice and dose of cardiovascular medications should be based on the desired therapeutic effects on the cardiovascular system. Note that increasing DO$_2$ *beyond* normal does not improve outcomes.[31-33]

While blood pressure is a universal measure of circulation adequacy, and often a therapeutic target, there are few randomised controlled trials evaluating the ideal MAP. Choice of ideal MAP remains empirical and should be based on the clinician’s assessment of the minimum pressure thought to represent adequate blood flow. Current guidelines advocate a target MAP ≥65 mm Hg, but acknowledge this should be altered depending upon patient circumstances (e.g. chronic hypertension, penetrating trauma and head injury).[1] Since these guidelines were last updated, a large randomised clinical trial in critically ill older adults found mortality did not differ with target MAP 60-65 mm Hg compared to a clinician-chosen MAP.[34] Interestingly the point estimates for most subgroups (including those with pre-existing hypertension) favoured those in the lower MAP target. Similarly, a clinical trial of patients with septic shock randomised to have MAP 65–70 mm Hg or 80–85 mm Hg found no difference in mortality, but higher need for catecholamines and higher prevalence of atrial fibrillation in the higher MAP group.[35] Our understanding of how best to assess and support the circulation remains an area of important ongoing investigation.

Manage precipitating illness or injury

As the circulation is being resuscitated, the cause of the circulatory disturbance needs to be identified and corrected. Time to definitive treatment of the cause of shock is related to survival. This has been clearly illustrated in cardiogenic shock (time to reperfusion),[36] haemorrhagic shock (time to haemorrhage control) [37] and septic shock (time to appropriate antibiotics). [38]

Monitoring

Outcomes from shock are best when it is recognised early and when the patient is managed in an environment that closely monitors clinical signs, physiological parameters and response to resuscitation (i.e. an ICU). Clinical monitoring involves frequent assessment of heart rate, invasive arterial blood pressure, central venous pressure (CVP), respiratory rate, conscious state, urine output, peripheral perfusion and temperature. As there is no 'gold standard' measure of shock, multiple parameters should be assessed repeatedly to determine the adequacy of resuscitation and treatment. [39], [40]

Whilst CVP is an index of preload, it bears a variable relationship to venous volume, as it is dependent on location of the catheter to the right atrium, intra-thoracic pressures, venous compliance, position of the patient and tricuspid valve competence. Thus, CVP is a guide to the *pressure* status of the venous system rather than a measure of intravascular *volume* and preload. The CVP does not predict whether administering a volume of fluid will change cardiac output or oxygen delivery. [41-44]

Central venous cannulae are available that contain an oximeter in the tip that measures O_2-Hb saturation of central venous blood ($ScvO_2$). An $ScvO_2 \geq 70\%$ has been proposed as a resuscitation goal. [45] However, $ScvO_2$ is a general measure of global O_2 demand, does not measure the impact of coronary venous blood (from the coronary sinus), and inadequate DO_2 may still occur despite a normal or high $ScvO_2$ (via anatomical shunts, microcirculation shunting). Similarly, the arterial–central venous difference in CO_2 has been used as a measure of perfusion and values >6 mm Hg can represent increased metabolic demand, but this is not yet proven to be a reliable index to guide resuscitation. [46]

Measuring cardiac output in patients with shock is not required routinely. For most patients, clinical assessment provides adequate information regarding cardiac output. However, directly monitoring cardiac output may be necessary if a patient’s circulatory disturbance does not improve following initial treatment. There are an ever-increasing number of techniques available for estimating cardiac output, all with inherent strengths and limitations. Further discussion of haemodynamic monitoring will be outlined in subsequent chapters.

Monitoring haemodynamics with ultrasound is becoming an increasingly used and a recommended tool in ICU. [1, 47] Echocardiography plays an important role in diagnosing the type of shock and is the recommended investigation modality if clinical examination does not lead to a clear diagnosis. [1, 48] Other ultrasonic variables have been investigated to determine if they are clinically useful to guide the volume of fluid replacement. These include lung ultrasound, size of the inferior vena cava, ventricular volume at end-diastole, estimation of stroke volume and ejection fraction. [49] However, these techniques are operator and patient dependent, and their utility over repeated clinical assessment is unproven.

Blood gas, pH and lactate monitoring provide some guidance to the adequacy of cellular resuscitation. [45, 50] Of note, venous blood provides a reliable measure of metabolic but not respiratory disturbance. [51] Blood lactate levels, lactate clearance rates and falling base deficit are independently associated with poor outcomes [52-57] and are a better predictor of mortality than DO_2 or VO_2. [58] However, lactate is not specific for shock as elevated levels may also occur with liver failure (reduced lactate metabolism), thiamine deficiency (inhibits pyruvate dehydrogenase), lactate administration (in dialysis fluids), catecholamine administration (β-agonists) and prolonged exercise. Elevated blood lactate levels may also reflect regional dysoxia of an isolated anatomical organ or tissue (e.g. limb or bowel ischaemia) that may not necessarily be associated with a global circulatory disturbance. The role of targeting therapies to lactate clearance or base excess also remains uncertain. [59, 60]

Standard ICU monitoring techniques focus on the assessment of the macrocirculation. There is growing interest in how the microcirculation can be monitored. Microscopic analysis of the circulation with orthogonal polarisation spectral (OPS) and sidestream dark field (SDF) imaging provide fascinating insights into the microcirculatory status, and further developments are underway to understand how they may integrate into clinical practice.[61] Capillary refill time of the distal phalanx can provide a simple clinical surrogate of the microcirculation. A trial of resuscitation guided by capillary refill time compared to a lactate-guided strategy revealed less organ dysfunction and a strong signal toward mortality benefit.[62, 63] While an interesting finding, it is important to highlight that assessing and managing shock should be based on concurrent and repeated assessment of multiple physiological and clinical parameters.

Haemodynamic monitoring

Denzil Gill, Christopher Peter Nickson, Kevin Pathmanathan and Sarah Wesley

Introduction

Haemodynamic monitoring observes the functions of the cardiovascular system and determines whether adequate organ perfusion is maintained. The frequent or continuous measurement of physiologic variables provided by haemodynamic monitoring is used to detect cardiovascular insufficiency, identify contributing factors and guide therapeutic interventions: including choice of therapy; assessment of response to therapy; determination of therapeutic endpoints; and detection of complications. Intensive care practice has trended towards the use of less-invasive monitoring. This reflects advances in technology, the desire to avoid complications and the lack of data demonstrating improved survival with more invasive techniques.

Unfortunately, the ideal haemodynamic monitoring system does not exist (see Box 24.1). Current haemodynamic monitoring systems provide bedside clinicians with measures of pressure and flow within the cardiovascular system that are inexact surrogates of preload, contractility and afterload. These parameters are measured or derived from systemic or pulmonary arterial blood pressure (BP), volume or pressure indices of cardiac filling, stroke volume (SV) or cardiac output (CO) and various markers of tissue wellbeing.

Box 24.1

Characteristics of an ideal haemodynamic monitoring system [1]

Provides measurement of relevant variables
Provides accurate and reproducible measurements
Provides interpretable data
Is easy to use
Is readily available
Is operator-independent
Provides continuous measurement and has a rapid response-time
Causes no harm
Is cost-effective
Provides information that guides therapy
Can be used in different critical settings, including during patient transport

Modified from Table 2 of Vincent JL, Rhodes A, Perel A, et al. Clinical review: update on hemodynamic monitoring–a consensus of 16. *Crit Care* . 2011;15(4):229. doi: 10.1186/cc10291 .

This chapter describes principles of haemodynamic monitoring relevant to clinical use. It outlines the role of clinical evaluation and focuses on monitoring techniques based on the measurement of pressures (systemic arterial, central venous and pulmonary arterial) and flow (CO). Functional haemodynamic monitoring, including the prediction of fluid responsiveness and monitoring of perfusion in the microcirculation are also discussed.

Principles of Haemodynamic Monitoring in Clinical Practice

Which haemodynamic monitoring approach is preferred depends on the context. Important contextual factors include the patient and the nature of their illness, the critical care setting, the expertise of the treating clinicians and the availability of different devices. Regardless, common principles apply.[1]

1. Haemodynamic monitoring alone does not improve patient outcomes. The data provided must be accurate, correctly interpreted and used to guide effective therapies.
2. Optimal haemodynamic 'targets' are not universal and need to be individualised for each patient.
3. Information should be integrated from multiple sources. History and examination findings are valuable, all measurement sources are subject to error, and different monitors may complement or corroborate one another when there is uncertainty.
4. Absolute values are less important than trends over time, with particular attention given to changes following therapeutic interventions.

Clinical Evaluation

The detection of circulatory insufficiency integrates clinical, haemodynamic and laboratory data. Clinical signs are often non-specific and may be absent in younger patients with greater compensatory reserve but must not be missed when present. Clinical features of shock are discussed in Chapter 23 , and microcirculatory dysfunction is discussed in a later section. Laboratory data, such as hyperlactataemia, may be relevant to haemodynamic assessment (see Chapter 57).

Standard ICU monitoring can provide important information to aid haemodynamic assessment. ECG monitoring may indicate dysrhythmias or ischaemia contributing to haemodynamic instability. In addition to identifying hypoxaemia, the pulse oximetry trace is often damped in shocked states with poor peripheral perfusion. Finally, end-tidal CO_2 ($ETCO_2$) provides an indirect assessment of transpulmonary flow and decreases with low CO or poor lung perfusion, especially pulmonary embolus (PE).

The Physical Basis of Cardiovascular Pressure Monitoring

Complex interactions between the blood, heart and vasculature generate cyclical pressure changes and pulsatile blood flow. The main determinant of pressure within blood vessels is the resistance to stretch (elastance) of the vessel wall by the blood within the vessel. As the SV is ejected from the ventricle during systole, the volume of blood in the proximal arteries increases and the elastic fibres of the arterial wall stretch producing a recoil force. At the end of systole when the aortic and pulmonary valves are closed, the energy of the recoil force stored within the elastic fibres of the vessel wall acts on the column of blood to produce forward flow. The rate of flow depends on the elastance of the vessel walls and the resistance of the vessels emptying the arterial tree. As the column of blood flows, the pressure in the proximal arteries falls during cardiac diastole to a nadir that is determined by vessel compliance and vascular tone. [2]

Principles of Invasive Central Venous and Arterial Pressure Monitoring Systems

Continuous, direct measurement of systemic arterial, central venous and pulmonary arterial pressures in intensive care patients requires an intra-vascular catheter connected to a transducer system. The intra-vascular catheter is connected via a short length of non-compliant (stiff), fluid-filled and bubble-free tubing to an external pressure sensor. The tubing delivers a constant infusion of 2–4 mL/h of plain or heparinised 0.9% saline from a bag pressurised to 300 mm Hg (mm Hg can be converted into kilopascals by multiplying by 0.13). [2] This prevents occlusion of the cannula with thrombus and ensures constant flow through the pressure sensor.

Pressure sensors are transducers that convert the kinetic and potential energy of the moving column of blood into electrical energy proportional to pressure within the sensor. Based on strain-gauge principles, they have a small diaphragm in communication with the fluid column that distorts in response to transmitted pressure waves, lengthening or shortening small wires in a circuit on the diaphragm and changing the resistance within the wires. Alterations in resistance are measured using a Wheatstone bridge which produces an electrical signal containing complex wave components that are processed by Fourier analysis to produce a waveform that is displayed on the monitor.[3,4] The displayed waveform is the summation of a series of mechanical pressure signals moving as multiple sine waves (multiple harmonics). The sine wave occurring at the rate of the pulse is the fundamental frequency (first harmonic) and each subsequent harmonic is a multiple of the fundamental frequency (e.g. the second harmonic occurs at twice the frequency of the fundamental frequency). Analysis of six to ten harmonics is required to construct the displayed arterial waveform. Examples of central venous, systemic arterial and pulmonary arterial pressure waveforms are shown in Fig. 24.1 .

The four-part diagram contains horizontally aligned waveform tracings labelled from top to bottom as E C G, A R T, C V P, and P A P. The top waveform is labelled E C G and shows a standard cardiac cycle with labelled P, Q, R, S, and T waves. Arrows at the top denote the phases of diastole and systole. The second waveform, labelled A R T, represents arterial pressure with a sharp upstroke for systolic rise, a peak, and a downstroke ending in a dicrotic notch, followed by a diastolic decline. The third waveform, labelled C V P, presents a sequence of pressure deflections labelled A, C, and V waves interspersed with X descent and Y descent phases. The fourth waveform, labelled P A P, represents pulmonary artery pressure and shows a systolic rise and diastolic decline, labelled P A systolic and P A diastolic respectively. Each waveform has its own vertical pressure scale ranging from 0 millimetres of mercury to a maximum value, with 200 for A R T, 15 for C V P, and 30 for P A P. The diagram exhibits the temporal alignment and pressure dynamics across the cardiac cycle.

FIG. 24.1 Example of systemic arterial pressure (ART), central venous pressure (CVP) and pulmonary arterial pressure (PAP) waveforms. Timing relative to the electrocardiograph (ECG) waveform is shown. In brief, the components of the CVP waveform represent atrial contraction (A), closing and bulging of the tricuspid valve (C), atrial relaxation and downward movement of the tricuspid valve during ventricular contraction (X descent), passive filling of atrium with tricuspid valve still closed (V) and ventricular filling with opening of the tricuspid valve (Y descent).

Calibration and Zeroing

Modern transducers are electrically calibrated during manufacture and require no further internal calibration during use. By convention, zeroing (zero calibration) to atmospheric pressure occurs while levelling with the phlebostatic axis (the mid-axillary line in the fourth intercostal space corresponds to the level of the right atrium), which sets the arterial pressure monitor to a baseline reference value for that patient. Changing the transducer height relative to the patient will therefore alter the measured pressure. Lowering the transducer relative to the phlebostatic axis overestimates pressure, and vice versa, with a 10 cm change in transducer height causing a 7.5 mm Hg change in measured pressure. [5]

Dynamic Response of Pressure Measuring Systems

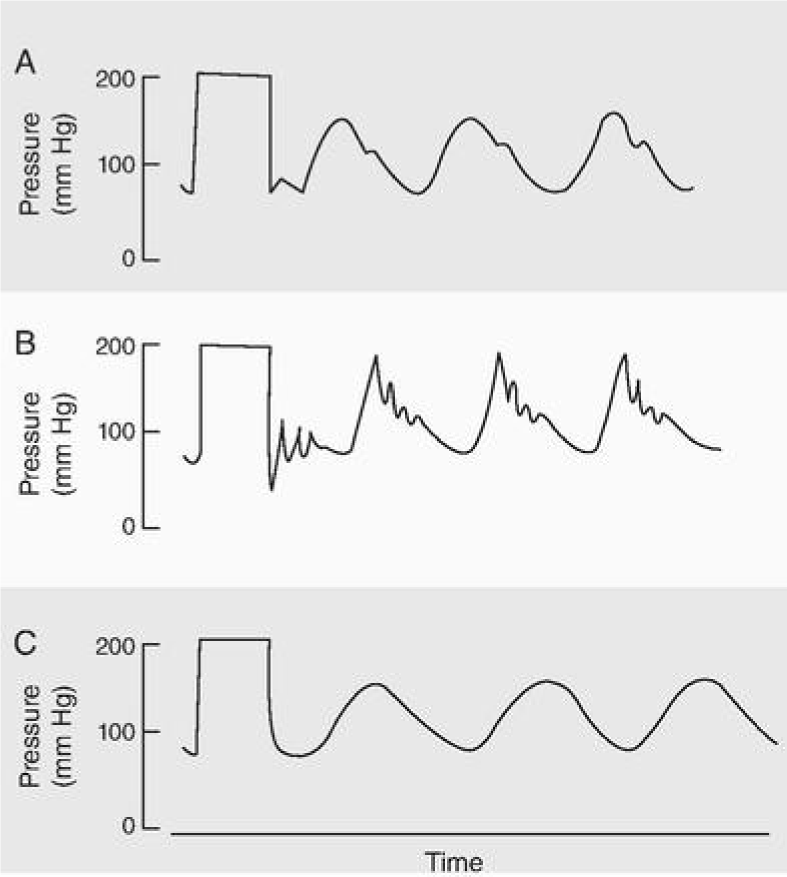
The dynamic response of pressure measuring systems refers to how well the system can accurately and rapidly detect and display changes in pressure over time. It is influenced by fluid harmonics, resonance and damping and will depend on the type of pressure being measured. For example, the measurement of arterial pressures will require a greater dynamic response than the measurement of venous pressures. To accurately produce the arterial BP waveform for heart rates up to 180/min (3/s or 3 Hz) using 10 harmonics (10 times the pulse rate or fundamental frequency) will require a dynamic response above 30 Hz.

Resonance

Resonance refers to the amplification or reinforcement of vibrations in an oscillating system. All materials oscillate (vibrate) at a natural resonant frequency as they absorb and release energy. If the natural resonant frequency of the cannula and tubing in the transducer system is too low, it becomes close to the high-frequency components of the moving pressure waveform. In this situation the system will resonate, amplifying the oscillations and causing distortion of the electrical output signal. The cannula-transducer system will then tend to overread the systolic pressure, underread the diastolic pressure and widen the pulse pressure. The natural resonant frequency of the system is also lowered, and the signal is distorted when the stiff tubing connecting the cannula to the transducer is too long. [6] To avoid this the materials used for invasive pressure monitoring cannulae and tubing are designed to have a natural resonant frequency above 40 Hz and the tubing lengths are kept short. [5]

Damping

Damping is the tendency to reduce vibrations or noise in a system and refers to any property of an oscillatory system that reduces the amplitude of oscillations and rate of change of signal between the patient and transducer. Partial occlusion of the cannula with thrombus, the presence of bubbles in the saline column, loose connections or the use of soft, compliant tubing, all tend to absorb energy and cause overdamping. This results in smaller amplitude peaks and troughs in the waveform with underestimation of systolic pressures and overestimation of diastolic pressures, although mean arterial pressure (MAP) will still be accurate.[4,5] Damping is assessed clinically using a square wave or fast flush test (Fig. 24.2).



The three-part diagram contains horizontal pressure versus time waveforms labelled A, B, and C. Each graph has a vertical axis labelled pressure in millimetres of mercury, ranging from 0 to 200, and a horizontal axis labelled time. Part A shows an initial rectangular step increase in pressure, followed by a series of uniform, rounded oscillations with consistent amplitude and spacing. Part B begins with a similar rectangular pressure rise, followed by a series of rapid, irregular oscillations that vary in amplitude and frequency, displaying a more erratic waveform pattern. Part C also starts with a rectangular pressure increase, followed by large, smooth, regular, and rounded oscillations with stable amplitude and frequency over time. The visual presents three different waveform profiles, each representing distinct pressure behaviour patterns across time in a comparative format.

FIG. 24.2 Assessment of arterial line waveform damping using a fast flush test. [7] The fast flush test is performed by opening the flush valve on the pressure transducer line allows the pressure in the pressure bag (300 mm Hg) of the continuous flush line to be transmitted to the pressure transducer. When the flush valve is abruptly released, the valve closes and oscillations are induced in the pressure transducer system. With optimal damping (A), the system will return to the measured pressure with only one or two oscillations of overshoot. In an underdamped system (B) the pressure waveform will overshoot and oscillate above and below the baseline several times before settling. In an overdamped system (C) the waveform will return to baseline over a longer period but without oscillations. (Adapted from Figure 2 of Stoker MR. Common errors in clinical measurement. *Anaesth Intensive Care Med* . 2008;9(12):553-558. doi: 10.1016/j.mpaic.2008.09.016 .)

Systemic Arterial Blood Pressure Measurement

When BP is measured, the values reported include:

- Systolic blood pressure (SBP) – maximum pressure measured during ventricular systole.
- Diastolic blood pressure (DBP) – minimum pressure measured during diastole.
- Mean arterial pressure (MAP) – time-averaged pressure over one cardiac cycle (systole and diastole).
- Pulse pressure (PP) – difference between SBP and DBP ($PP = SBP - DBP$).

The MAP is the most relevant of these variables for several reasons:

1. *MAP is least dependent on the measurement site.* As the pulse waves propagate from the aortic root to the distal arterial tree, summation with reflected waves gives rise to distal wave amplification. Consequently, the more distal from the aortic root the BP is measured: the systolic portion of the wave becomes narrower and reaches a higher SBP; the dicrotic notch due to aortic valve closure is progressively delayed and eventually lost; the DBP becomes progressively lower; and the pulse pressure is progressively wider. The SBP can be up to 20 mm Hg higher in the radial artery when compared to the proximal aorta. [8] However, the MAP is minimally affected by distal wave amplification and insertion of arterial lines at multiple sites shows consistent agreement between MAP values.
2. *MAP is least affected by damping during invasive measurement.*
3. *MAP is least dependent on the method of measurement.* When the non-invasive methods of BP measurement are compared to measurement by direct arterial cannulation, the MAP values are often comparable despite large variation in SBP and DBP recordings.
4. *MAP determines tissue blood flow via autoregulation (except for perfusion of the left ventricle (LV) where coronary blood flow is determined by DBP).* Autoregulation of blood flow occurs to maintain a constant MAP in most tissues. The relationship between MAP, flow and resistance is the fluid hydraulic equivalent of Ohm’s law.

$$\mathrm{MAP} = (\mathrm{CO} \times \mathrm{SVR}) + \mathrm{RAP}$$

where MAP is mean arterial pressure, CO is cardiac output, SVR is systemic vascular resistance and RAP is right atrial pressure.

Rearranging the equation demonstrates that flow is determined by the inflow and outflow pressure difference divided by the resistance to flow:

$$\mathrm{CO} = (\mathrm{MAP} - \mathrm{RAP})/\mathrm{SVR}$$

5. *MAP targets are reported as endpoints for resuscitation in guidelines for the management of patients with critical illness.* A MAP >65 mm Hg is recommended as a goal of therapy in patients with circulatory shock or sepsis; however, there is increasing recognition that a single MAP target is not appropriate for all patients, and patients with pre-existing hypertension may benefit from a higher MAP target.[9,10]

Direct (Invasive) Systemic Arterial Blood Pressure Measurement

Direct, systemic arterial BP measurement is performed using an intra-arterial cannula attached to a pressure transducer system and electronic monitor. It provides continuous BP monitoring and allows arterial blood gas sampling. It remains the mainstay for haemodynamic monitoring of intensive care patients and has several useful benefits (Box 24.2), despite a lack of evidence that the presence of an arterial cannula improves mortality in intensive care patients.[11] Relative contraindications to arterial cannulation include coagulopathy and vascular abnormality or disease.

Box 24.2

Benefits of direct systemic arterial pressure monitoring

Allows continuous monitoring and assessment of patients with haemodynamic instability and/or organ dysfunction

Allows titration of vasopressor or vasodilator agents to specified MAP targets to maintain adequate organ perfusion

Provides peri-operative monitoring for patients undergoing major surgical procedures (including during periods of non-pulsatile blood flow on cardiopulmonary bypass)

Allows monitoring of patients in whom non-invasive BP measurements have failed

Can be used to guide fluid resuscitation and assess fluid responsiveness in selected patients

Allows comparison of regional pressure and flow in different regions of the arterial circulation (for example in patients with aortic dissection)

Are more reliable than non-invasive BP measurements in patients with circulatory failure and/or arrhythmias

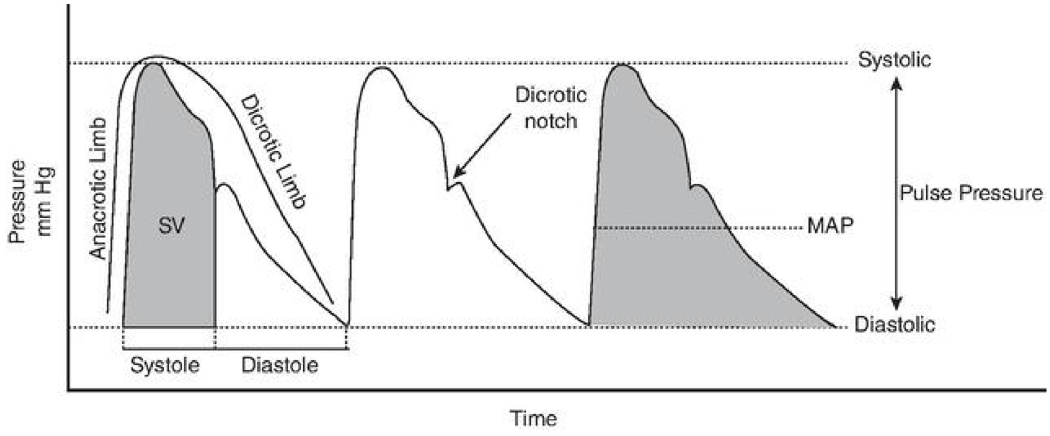
Provides access for repeated arterial blood gas sampling

Arterial cannulation can be performed using a modified Seldinger technique or direct cannulation, with or without the assistance of ultrasound guidance. Arterial cannulas are stiff walled to reduce damping and should not be larger than 20-gauge as larger cannulas may increase the risk of arterial thrombosis. The radial artery, due to ease of access and low risk of complications, is the most common site of arterial cannulation and the use of Allen’s test to assess collateral flow has largely been superseded by the use of ultrasound and vascular Doppler. Other common sites of arterial cannulation include the brachial, femoral and dorsalis pedis arteries, though other sites can be used. The choice of arterial cannulation site is based on the indication for monitoring, accessibility, anatomical considerations and the desire to minimise complications. Radial artery cannulation for example would not be considered for a patient undergoing radial arterial harvesting for coronary bypass grafting, or in a limb where an arteriovenous fistula is present or planned. Multiple concurrent sites of arterial cannulation are appropriate in select patients for example patients presenting with aortic dissection where there is variation in blood flow to the limbs depending on the position of the dissection flap. The brachial artery waveform more closely reflects pressures in the proximal aorta than the radial or femoral arterial sites which are more affected by distal wave amplification; however, brachial artery cannulation is not recommended in paediatric patients.

Complications of arterial cannulation are shown in Table 24.1 and can be largely avoided by vigilance and diligent cannula care. Tubing connected to arterial lines should be clearly labelled near injecting port sites to prevent inadvertent intra-arterial injection of drugs intended for intravenous administration. Arterial cannulae should be removed when no longer required and replaced only when necessary. Distal perfusion should be routinely checked on every shift, and the cannula removed if there is persistent blanching, coolness, delayed capillary refill, loss of distal pulses or evidence of raised compartment pressures. Thrombosis is common with temporary occlusion of the radial artery identified in up to 20% of patients.[12] The risk of thrombosis can be reduced by using smaller diameter cannulas relative to the size of the artery, removing cannulae when not required and avoiding multiple traumatic attempts at insertion. Radial artery thrombosis usually resolves with the removal of the arterial cannula, and blood flow re-establishes within a few weeks. In patients with distal limb ischaemia prompt vascular surgical consultation should be sought to optimise reperfusion and minimise the risk of permanent injury requiring amputation. Femoral arterial cannulation has higher reported incidences of catheter-related local infections (CRLI) (3.02 vs. 0.75 per 1000 catheter days) and catheter-related bloodstream infections (CRBSI) (1.92 vs. 0.25 per 1000 catheter days) than radial arterial cannulation.[13]

Table 24.1

Systemic artery cannulation allows a continuous graphical display of the arterial waveform as well as the heart rate, SBP, DBP and MAP (Fig. 24.3). Additional information such as SV, CO, pulse pressure variation (PPV) and stroke volume variation (SVV) can be estimated by various devices using pulse wave analysis of the arterial waveform and will be discussed later in the chapter.



The labelled arterial pressure waveform graph presents a pressure versus time waveform labelled cardiovascular cycle components. The vertical axis is labelled pressure in millimetres of mercury, and the horizontal axis is labelled time. Each waveform cycle includes a rapid upstroke labelled anacrotic limb, followed by a descending dicrotic limb. The shaded area under the systolic portion of the curve is labelled S V, representing stroke volume. The descending portion features a marked inflection labelled dicrotic notch. The entire cardiac cycle is divided into systole and diastole along the lower edge of the waveform. A horizontal bracket on the right side marks the difference between systolic and diastolic levels as pulse pressure, while a dotted line across one waveform marks M A P for mean arterial pressure. The diagram illustrates repeated waveform cycles with consistent labelling of key physiological pressure points and phases across time.

FIG. 24.3 Arterial pressure waveform. The anacrotic and dicrotic limbs, corresponding to the upstroke and downstroke of the waveform are shown, as well as the components of the waveform corresponding to systole and diastole. The area under the systolic

portion of the waveform is proportional to the SV. Mean arterial pressure (MAP) is calculated from the time-averaged area under the entire waveform, and the points corresponding to systolic (SBP) and diastolic (DBP) blood pressure are indicated. Pulse pressure (PP) is calculated as: PP = SBP − DBP.

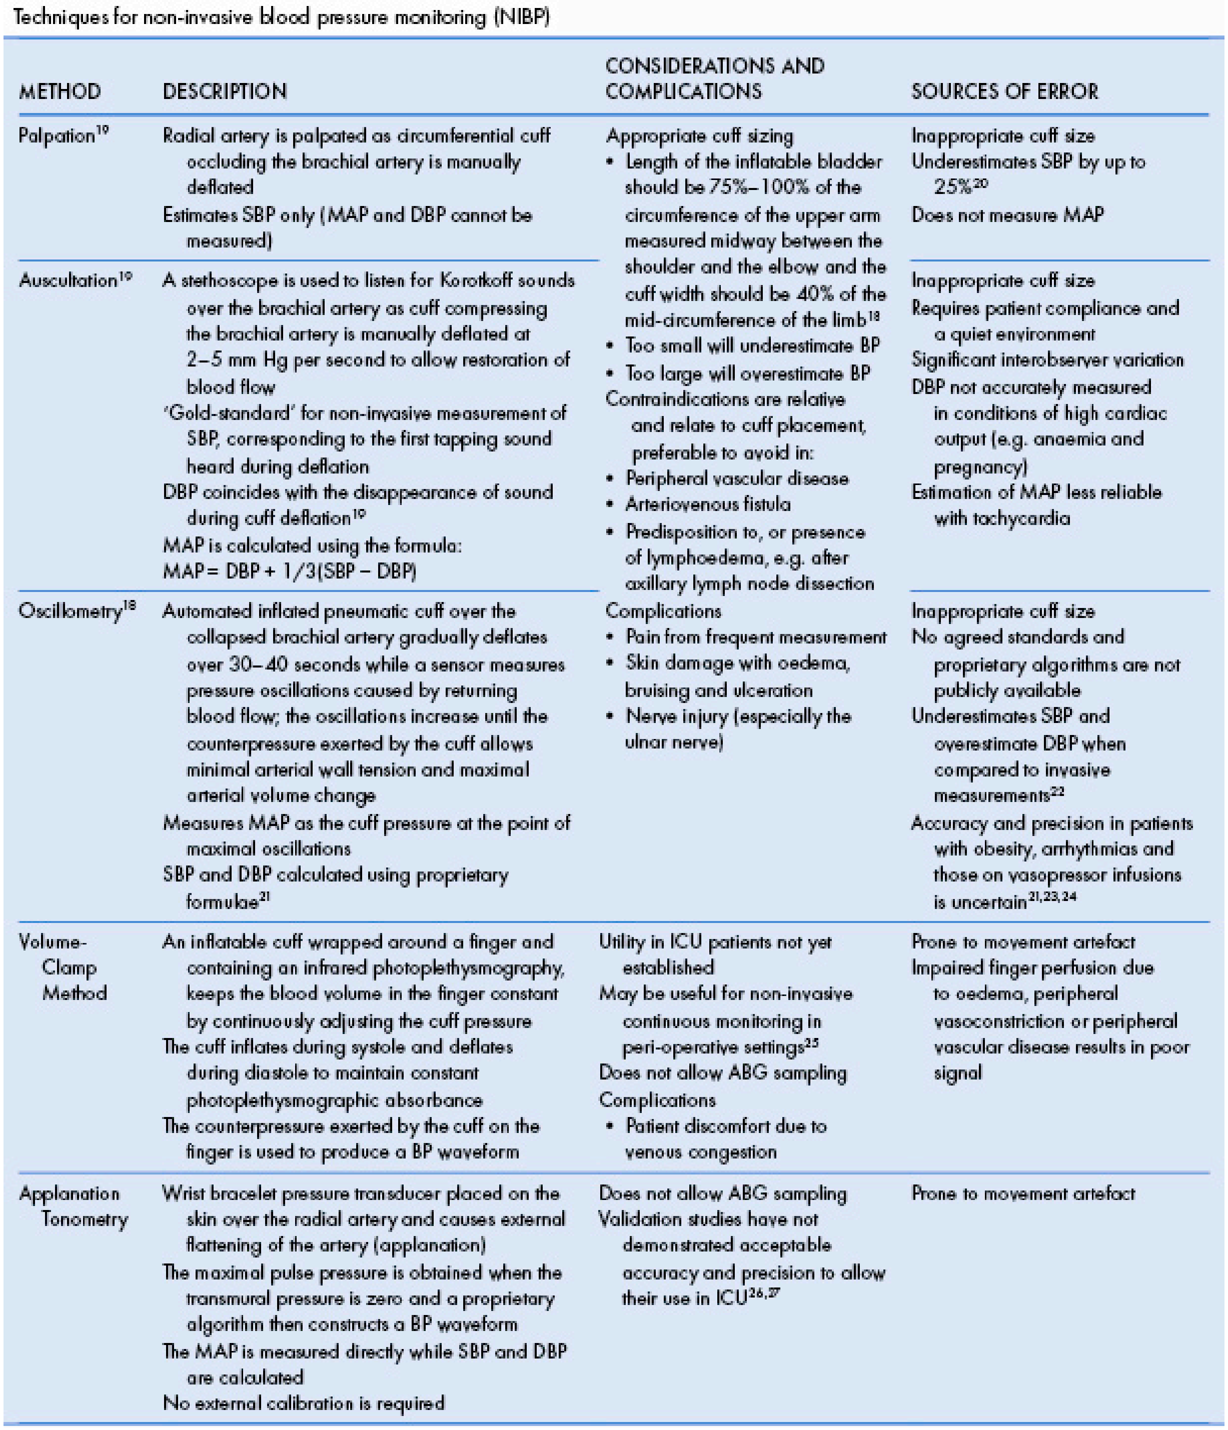
The main purpose of continuous arterial BP monitoring is to help maintain a BP sufficient to ensure adequate tissue perfusion. Hypotension leading to inadequate end-organ perfusion is associated with increased mortality and the risk of patient death increases as the time spent with a MAP <65 mm Hg increases.[14,15] Current guidelines for management of circulatory shock and sepsis, recommend a MAP >65 mm Hg; however, this target may need to be higher in some patients, particularly those with pre-existing hypertension.[9,10] The SEPSISPAM study failed to show a mortality benefit when targeting a higher MAP (80–85 mm Hg compared to 65–70 mm Hg) during the resuscitation of patients with septic shock and it is likely that the target MAP for most individual patients will lie within the 65–85 mm Hg range.[16,17] Achieving the desired MAP in an individual patient requires the clinician to balance the use of fluids, vasopressors and inotropes, the amount and combination of each being dependent on the individual patient and their underlying pathophysiology.

Indirect (Non-Invasive) Arterial Blood Pressure Measurement

Indirect, non-invasive blood pressure (NIBP) measurements can be considered in relatively stable patients. They are usually performed intermittently, and the required frequency of BP measurement will determine whether it is more practical to insert an arterial line and perform direct, continuous invasive pressure measurements. Automated oscillometric devices are now used in most pre-hospital and hospital settings. The oscillometric NIBP forms the basis for guidelines for the diagnosis and treatment of conditions such as hypertension[18] and provides the ward-based observations recorded on track-and-trigger early warning systems used by hospitals to activate rapid response teams. However, most ward observation charts record SBP and DBP but do not record MAP, the variable most accurately measured by oscillometric devices.

Recent advances have also seen the development of technologies that can produce continuous NIBP readings aimed at avoiding the need for invasive arterial lines. The techniques used for intermittent and continuous NIBP measurement are described in Table 24.2 .

Table 24.2



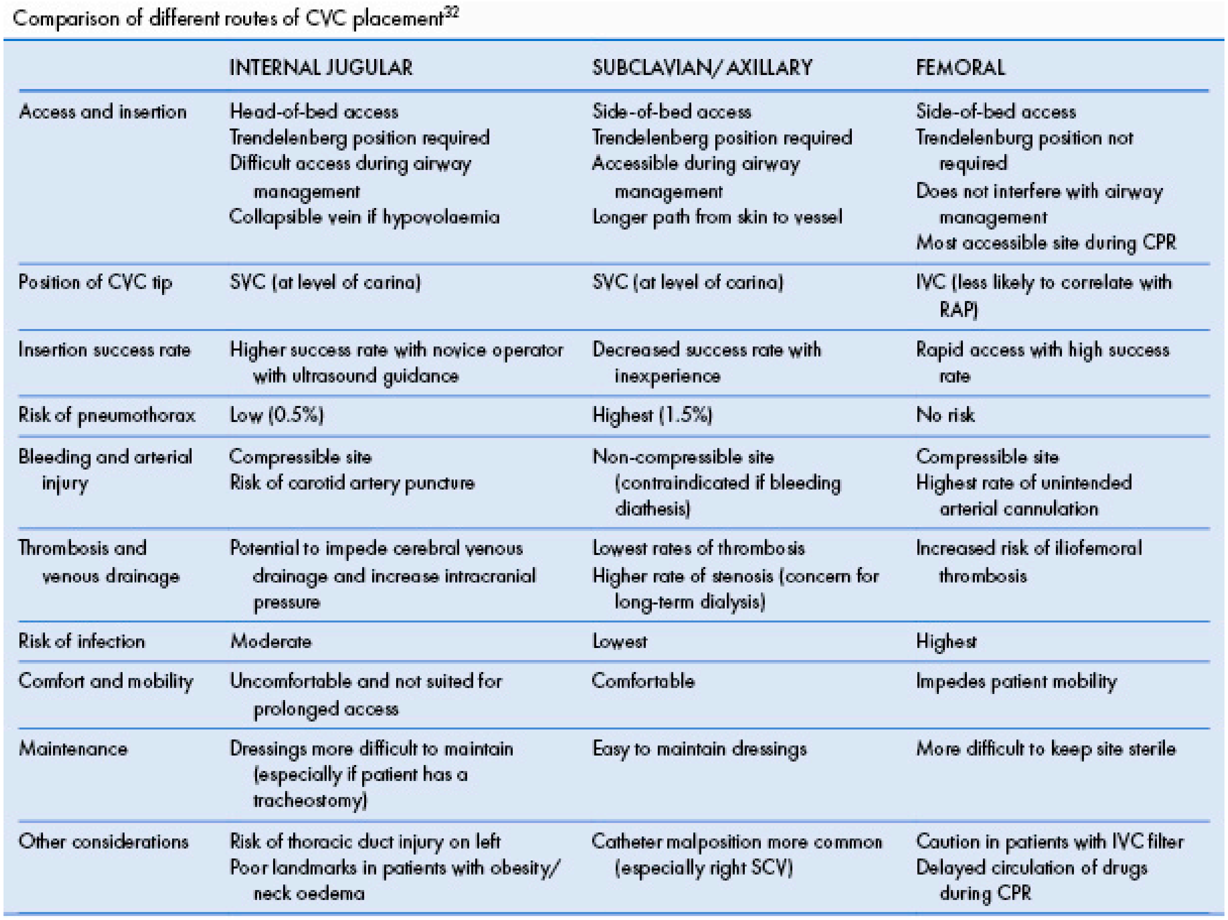
Techniques for non-invasive blood pressure monitoring (NIBP)

METHOD	DESCRIPTION	CONSIDERATIONS AND COMPLICATIONS	SOURCES OF ERROR
Palpation[19]	Radial artery is palpated as circumferential cuff occluding the brachial artery is manually deflated Estimates SBP only (MAP and DBP cannot be measured)	Appropriate cuff sizing • Length of the inflatable bladder should be 75%–100% of the circumference of the upper arm measured midway between the shoulder and the elbow and the cuff width should be 40% of the mid-circumference of the limb[18] • Too small will underestimate BP • Too large will overestimate BP Contraindications are relative and relate to cuff placement, preferable to avoid in: • Peripheral vascular disease • Arteriovenous fistula • Predisposition to, or presence of lymphoedema, e.g. after axillary lymph node dissection Complications • Pain from frequent measurement • Skin damage with oedema, bruising and ulceration • Nerve injury (especially the ulnar nerve)	Inappropriate cuff size Underestimates SBP by up to 25%[20] Does not measure MAP
Auscultation[19]	A stethoscope is used to listen for Korotkoff sounds over the brachial artery as cuff compressing the brachial artery is manually deflated at 2–5 mm Hg per second to allow restoration of blood flow 'Gold-standard' for non-invasive measurement of SBP, corresponding to the first tapping sound heard during deflation DBP coincides with the disappearance of sound during cuff deflation[19] MAP is calculated using the formula: MAP = DBP + 1/3(SBP − DBP)		Inappropriate cuff size Requires patient compliance and a quiet environment Significant interobserver variation DBP not accurately measured in conditions of high cardiac output (e.g. anaemia and pregnancy) Estimation of MAP less reliable with tachycardia
Oscillometry[18]	Automated inflated pneumatic cuff over the collapsed brachial artery gradually deflates over 30–40 seconds while a sensor measures pressure oscillations caused by returning blood flow; the oscillations increase until the counterpressure exerted by the cuff allows minimal arterial wall tension and maximal arterial volume change Measures MAP as the cuff pressure at the point of maximal oscillations SBP and DBP calculated using proprietary formulae[21]		Inappropriate cuff size No agreed standards and proprietary algorithms are not publicly available Underestimates SBP and overestimate DBP when compared to invasive measurements[22] Accuracy and precision in patients with obesity, arrhythmias and those on vasopressor infusions is uncertain[21,23,24]
Volume-Clamp Method	An inflatable cuff wrapped around a finger and containing an infrared photoplethysmography, keeps the blood volume in the finger constant by continuously adjusting the cuff pressure The cuff inflates during systole and deflates during diastole to maintain constant photoplethysmographic absorbance The counterpressure exerted by the cuff on the finger is used to produce a BP waveform	Utility in ICU patients not yet established May be useful for non-invasive continuous monitoring in peri-operative settings[25] Does not allow ABG sampling Complications • Patient discomfort due to venous congestion	Prone to movement artefact Impaired finger perfusion due to oedema, peripheral vasoconstriction or peripheral vascular disease results in poor signal
Applanation Tonometry	Wrist bracelet pressure transducer placed on the skin over the radial artery and causes external flattening of the artery (applanation) The maximal pulse pressure is obtained when the transmural pressure is zero and a proprietary algorithm then constructs a BP waveform The MAP is measured directly while SBP and DBP are calculated No external calibration is required	Does not allow ABG sampling Validation studies have not demonstrated acceptable accuracy and precision to allow their use in ICU[26,27]	Prone to movement artefact

Central Venous Pressure

Central venous pressure (CVP) is measured by a central venous catheter (CVC) connected to a transducer, which is connected to fluid-filled tubing supplied by a pressurised fluid bag in a similar fashion to that used for measurement of intra-arterial pressure. The most common routes for central venous access are via the subclavian (SCV), internal jugular (IJV) and femoral veins. Each has advantages and disadvantages (see Table 24.3), and site selection should be tailored to the individual patient. CVCs are inserted using a modified Seldinger technique, and ultrasound guidance (see Chapter 40) is recommended.[28,29] Relative contraindications to CVC insertion are listed in Box 24.3 . As with other intra-vascular catheters, aseptic insertion and daily maintenance with careful attention to dressings, catheter patency and potential complications is vital[30] (see Table 24.1). Rates of central line-associated bloodstream infection (CLABSI) should be minimised and ANZICS advocates for a target of <1/1000 catheter days.[31]

Table 24.3



Comparison of different routes of CVC placement[32]

	INTERNAL JUGULAR	SUBCLAVIAN/AXILLARY	FEMORAL
Access and insertion	Head-of-bed access Trendelenberg position required Difficult access during airway management Collapsible vein if hypovolaemia	Side-of-bed access Trendelenberg position required Accessible during airway management Longer path from skin to vessel	Side-of-bed access Trendelenburg position not required Does not interfere with airway management Most accessible site during CPR
Position of CVC tip	SVC (at level of carina)	SVC (at level of carina)	IVC (less likely to correlate with RAP)
Insertion success rate	Higher success rate with novice operator with ultrasound guidance	Decreased success rate with inexperience	Rapid access with high success rate
Risk of pneumothorax	Low (0.5%)	Highest (1.5%)	No risk
Bleeding and arterial injury	Compressible site Risk of carotid artery puncture	Non-compressible site (contraindicated if bleeding diathesis)	Compressible site Highest rate of unintended arterial cannulation
Thrombosis and venous drainage	Potential to impede cerebral venous drainage and increase intracranial pressure	Lowest rates of thrombosis Higher rate of stenosis (concern for long-term dialysis)	Increased risk of iliofemoral thrombosis
Risk of infection	Moderate	Lowest	Highest
Comfort and mobility	Uncomfortable and not suited for prolonged access	Comfortable	Impedes patient mobility
Maintenance	Dressings more difficult to maintain (especially if patient has a tracheostomy)	Easy to maintain dressings	More difficult to keep site sterile
Other considerations	Risk of thoracic duct injury on left Poor landmarks in patients with obesity/neck oedema	Catheter malposition more common (especially right SCV)	Caution in patients with IVC filter Delayed circulation of drugs during CPR

Box 24.3

Relative contraindications to central venous catheterisation

Obstructed vessel (e.g. thrombosis and tumour)
Haemorrhage from target vessel
Vascular abnormality (e.g. stenosis and malformation)
Overlying skin infection, burn, local trauma or other disease process
Severe bleeding diathesis (especially SCV as non-compressible site)
Unable to perform Trendelenberg positioning (IJV and SCV sites)
Uncooperative patient

CVP is the pressure measured within the central veins, usually the superior vena cava (SVC) close to the right atrium, and approximates right atrial pressure (RAP). [33] Normal CVP is 0–5 mm Hg in a healthy spontaneously breathing patient and up to 10 mm Hg during mechanical ventilation. The CVP has haemodynamic significance because RAP is a key determinant of venous return (VR) to the heart:

$$\mathrm{VR} = \left(\mathrm{MSFP} - -\mathrm{RAP}\right)/\mathrm{R}_{\mathrm{VR}}$$

where VR is venous return, MSFP is mean systemic filling pressure, RAP is right atrial pressure and R_{VR} is resistance to venous return.

VR is equivalent to CO because the heart pumps out all blood that is returned to it. [34] An elevated RAP tends to decrease VR, and thus CO. To maintain CO, the heart must decrease RAP. It does this due to the Frank-Starling relationship, which holds that the greater the myocardial stretch (or preload), the more strongly the myocardium will contract. Thus SV increases, and more blood is ejected from the heart, tending to return cardiac filling pressures to normal, however, beyond a certain degree of stretch (preload) there is no further increase. In a normal heart with normal valvular function, RAP is equal to the right ventricular end-diastolic pressure (RVEDP), which is a surrogate of right ventricular end-diastolic volume (RVEDV). RVEDV represents right ventricular (RV) preload, which is the degree to which ventricular myocytes are stretched prior to contraction, meaning that the CVP is also a surrogate for preload.

CVP Measurement and Waveform Analysis

Accurate measurement of the CVP requires a CVC to be placed with its tip in a central vein close to the right atrium, calibration of the monitoring system, appropriate damping and levelling. The transducer should be zero calibrated level with the phlebostatic axis. Measurement should occur at end-expiration so that there is no negative pressure effect from inspiration during unassisted spontaneous breathing or additional positive pressure effect (beyond PEEP) during positive pressure ventilation.[33] Ideally, if the CVP is intended as a surrogate for preload, it should be measured at the end of diastole (start of the C wave on the CVP waveform) so that it equates to RVEDP, however, most monitors provide a value that is a time-based average over the entire waveform. The normal CVP waveform is shown in Fig. 24.1 . Ultimately, the actual CVP measurement obtained includes the interplay of numerous physiological factors and sources of measurement error (see Table 24.4).

Table 24.4

Determinants of central venous pressure [35]

MEASUREMENT FACTORS	PHYSIOLOGICAL FACTORS
Location of CVC tip (e.g. RA, SCV, IVC) Levelling, zeroing and calibration Damping Frequency response of the system (shorter stiffer tubing preferred) Running averages rather than end-diastolic readings PEEP (PEEP of 10 cm H_2O usually increases CVP by ~3 cm H_2O, varies with lung compliance)	RAP Intra-vascular fluid volume Venous capacitance/tone MSFP RV and LV function and compliance Valvular function (e.g. tricuspid regurgitation) Pulmonary vascular resistance Intra-thoracic/pleural pressure Intra-abdominal pressure

Analysis of the CVP waveform is useful for:

1. Confirmation of correct placement of the CVC tip when a normal waveform is seen following insertion.

2. Diagnosing cardiac pathologies that manifest as waveform abnormalities (see Fig. 24.4).[36]
3. Assessment of RV function and monitoring of right heart failure.
4. Providing a semi-invasive method of estimating right-sided and pulmonary pressures in combination with echocardiography, for example after cardiac surgery or PE.

The illustration presents seven horizontal waveform panels arranged vertically, each showing an E C G or central venous pressure waveform labelled C V P. The first row labelled normal E C G displays a regular P, Q, R, S, and T wave pattern. The second row is labelled atrial fibrillation or flutter and shows a C V P waveform with absent A waves, prominent C and V waves, and variable wave morphology. The third row labelled A V dissociation presents a C V P waveform with large cannon A waves aligned with ventricular systole. The fourth row labelled tricuspid insufficiency shows a waveform with large V waves that merge with C waves and absent X descent. The fifth row labelled tricuspid valve stenosis features large A waves and slow Y descent. The sixth row labelled pericardial constriction or restrictive cardiomyopathy includes tall A and V waves, steep X descent, and steep Y descent. The seventh row labelled tamponade exhibits tall A and V waves, with absent or diminished Y descent. Vertical dashed lines are aligned across panels to highlight timing relationships across waveform events. Each panel is annotated with respective deflections including A, C, V waves, and descent labels, reflecting pressure changes associated with specific cardiac conditions.

FIG. 24.4 Important cardiac pathologies and their CVP waveforms. [36] Refer to Fig. 24.1 for explanation of normal CVP waveform components. (Adapted from Figure 2 of Bootsma IT, Boerma EC, de Lange F, et al. The contemporary pulmonary artery catheter. Part 1: placement and waveform analysis. *J Clin Monit Comput* . 2002;36:5–15. doi: 10.1007/s10877-021-00662-8 .)

CVP was also traditionally used to guide intravenous fluid administration. Unfortunately, clinical studies have failed to show predictive value for CVP in determining fluid responsiveness. [37] This is unsurprising as CVP is a surrogate for preload and, simply put, preload is not the same as preload responsiveness.[38] As a result, interest has shifted to using dynamic measures involving surrogates of CO (discussed in later sections). Extreme values of CVP are more likely to be useful, however, routinely using the CVP in isolation to guide fluid management is unwise.

Central Venous Oxygen Saturation

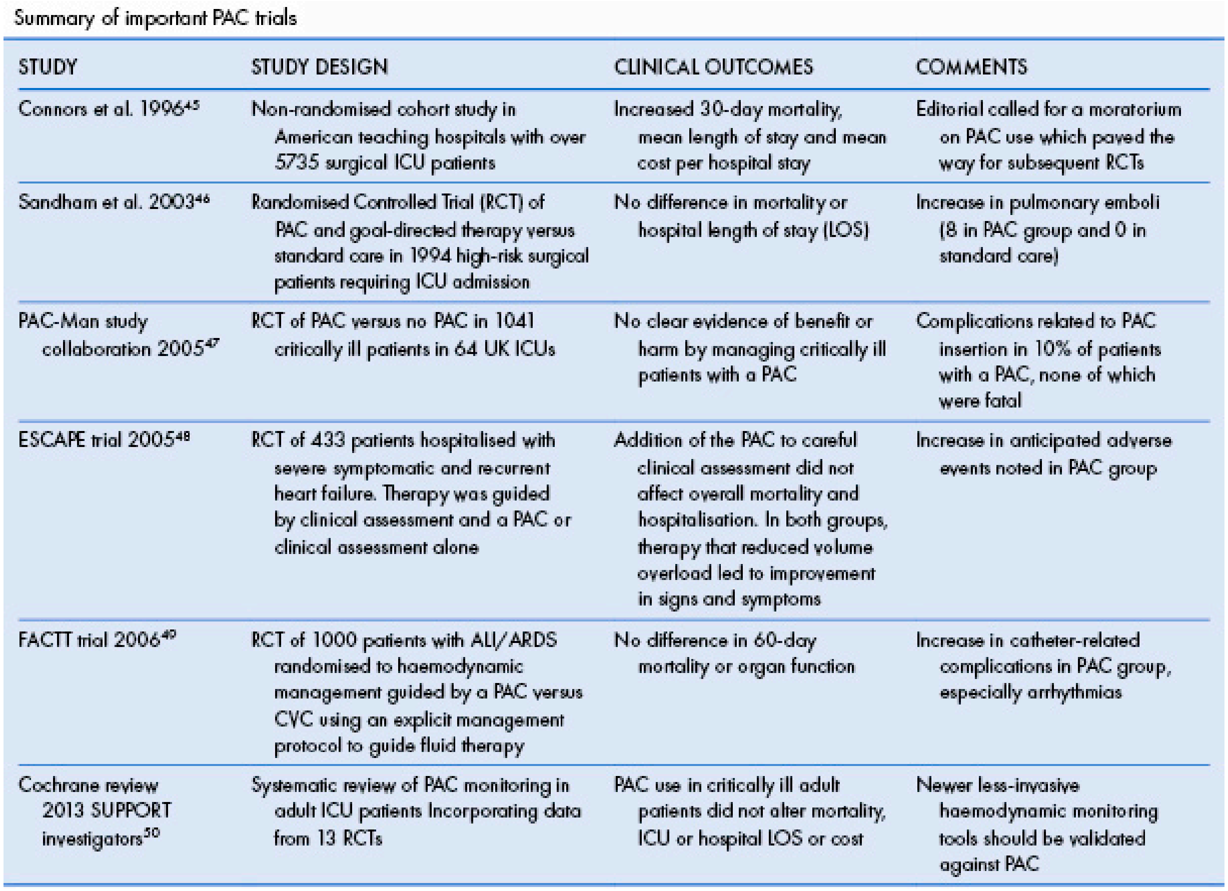
Central venous oxygen saturation ($S\text{cv}_{\text{O}_2}$) can be monitored using a CVC continuously or via blood gas analysis of samples. It has been proposed as a marker of tissue oxygen delivery (Chapter 38). $S\text{cv}_{\text{O}_2}$ rose to prominence as part of Early Goal-Directed Therapy (EGDT) protocols for sepsis management but large international multicentre trials and a consequent patient-level meta-analysis concluded that $S\text{cv}_{\text{O}_2}$, as part of EGDT, did not improve outcomes over usual care.[39]

Pulmonary Artery Catheter

Right-sided heart catheterisation using a flow-directed balloon-tipped catheter was introduced by Swan and colleagues in 1970[40] for bedside monitoring of cardiopulmonary haemodynamic variables. Despite widespread use, the pulmonary artery catheter (PAC) is invasive and remains contentious. Its use has declined due to the emergence of less-invasive monitoring, the increased use of echocardiography and the publication of clinical studies that have failed to show a positive outcome benefit from its use (see Table 24.5). Nevertheless, the PAC can be a useful diagnostic tool in certain circumstances (see Box 24.4) and expertise in insertion and interpretation remains valuable for intensivists. Interpretation of PAC data has the potential to alter or guide therapy towards improved outcomes in select cases, particularly in the most severely ill and injured patients[41] where newer, less-invasive methods of monitoring are less reliable and lack validation. More recently, non-randomised studies of patients with cardiogenic shock, have shown improved outcomes when a PAC is used to guide therapy.[42, 43] Nevertheless, PAC use needs to be balanced against the prospect of potentially serious complications.[44] Contraindications for insertion are similar to those for CVCs (see Box 24.3

). If known in advance, cardiac and vascular structural abnormalities should also be considered.

Table 24.5



Summary of important PAC trials

STUDY	STUDY DESIGN	CLINICAL OUTCOMES	COMMENTS
Connors et al. 1996[45]	Non-randomised cohort study in American teaching hospitals with over 5735 surgical ICU patients	Increased 30-day mortality, mean length of stay and mean cost per hospital stay	Editorial called for a moratorium on PAC use which paved the way for subsequent RCTs
Sandham et al. 2003[46]	Randomised Controlled Trial (RCT) of PAC and goal-directed therapy versus standard care in 1994 high-risk surgical patients requiring ICU admission	No difference in mortality or hospital length of stay (LOS)	Increase in pulmonary emboli (8 in PAC group and 0 in standard care)
PAC-Man study collaboration 2005[47]	RCT of PAC versus no PAC in 1041 critically ill patients in 64 UK ICUs	No clear evidence of benefit or harm by managing critically ill patients with a PAC	Complications related to PAC insertion in 10% of patients with a PAC, none of which were fatal
ESCAPE trial 2005[48]	RCT of 433 patients hospitalised with severe symptomatic and recurrent heart failure. Therapy was guided by clinical assessment and a PAC or clinical assessment alone	Addition of the PAC to careful clinical assessment did not affect overall mortality and hospitalisation. In both groups, therapy that reduced volume overload led to improvement in signs and symptoms	Increase in anticipated adverse events noted in PAC group
FACTT trial 2006[49]	RCT of 1000 patients with ALI/ARDS randomised to haemodynamic management guided by a PAC versus CVC using an explicit management protocol to guide fluid therapy	No difference in 60-day mortality or organ function	Increase in catheter-related complications in PAC group, especially arrhythmias
Cochrane review 2013 SUPPORT investigators[50]	Systematic review of PAC monitoring in adult ICU patients Incorporating data from 13 RCTs	PAC use in critically ill adult patients did not alter mortality, ICU or hospital LOS or cost	Newer less-invasive haemodynamic monitoring tools should be validated against PAC

Box 24.4

Indications for PAC monitoring [51]

Characterising complex haemodynamic changes, e.g. distributive, cardiogenic, hypovolaemic and obstructive shock (especially when TTE, TOE or Pulse Contour Analysis are unable to be used)

Differentiating cardiogenic from non-cardiogenic pulmonary oedema in respiratory failure

Guiding use of vasoactive drugs and fluid management in congestive cardiac failure and cardiogenic shock
Managing complex post-operative cardiac surgery patients with LV or RV impairment, or mechanical assist devices in situ
Diagnosing and managing pulmonary hypertension
Assessment and management of RV failure
Work up of patients being considered for cardiac and pulmonary transplantation

Measured Variables

The PAC is unique in its ability to measure RV and pulmonary arterial pressures directly at the bedside. The measured pressures and tracing obtained on insertion of a PAC are shown in Fig. 24.5 .

The schematic diagram of the right heart with overlaid pressure waveforms is obtained during right heart catheterization. At the centre, a simplified anatomical diagram traces the catheter path through the right atrium, right ventricle, pulmonary artery, and into the pulmonary artery wedge position. Each anatomical site is accompanied by a waveform representing pressure in millimetres of mercury. The waveform for the right atrium is labelled with A, C, and V waves as well as X and Y descents, with a pressure range of 0 to 5 millimetres of mercury. The right ventricle waveform shows sharp systolic peaks and troughs, ranging from 15 to 25 millimetres of mercury. The pulmonary artery waveform displays a higher baseline with a dicrotic notch and pressures from 15 to 25 systolic and 8 to 15 diastolic. The pulmonary artery wedge waveform appears smoother with smaller undulations and a pressure range of 6 to 12 millimetres of mercury. A label for diastolic step up is placed between the right ventricle and pulmonary artery waveforms. The waveforms are also displayed separately along the sides of the anatomical diagram to show regional pressure trends in context.

FIG. 24.5 Pressure waveforms generated during insertion of the pulmonary artery catheter. (Adapted from Figure 1 of Bootsma IT, Boerma EC, de Lange F, et al. The contemporary pulmonary artery catheter. Part 1: placement and waveform analysis. *J Clin Monit Comput* . 2002;36:5–15. doi: 10.1007/s10877-021-00662-8 .)

Pulmonary Artery Occlusion Pressure

Pulmonary artery occlusion pressure (PAOP) or pulmonary artery wedge pressure (PAWP) is the last value obtained when inserting a PAC. The PAOP should be measured at the end of expiration when pleural pressures are minimal, and ideally at the end of diastole using the ECG p wave as a marker. Once the PAOP value has been obtained the balloon should be deflated to allow blood flow past the tip of the PAC and re-establish a normal pulmonary arterial waveform. If this does not occur, the catheter has migrated distally and should be withdrawn until the waveform is re-established.

As the catheter is wedged in a distal tapering artery, the inflated balloon creates a static column of blood between the tip of the PAC and the pulmonary vein before it enters near the left atrium. The measured PAOP reflects the pulmonary venous circulation pressure and provides an indirect measurement of left atrial pressure which acts as a surrogate for left ventricular end-diastolic pressure (LVEDP). While PAOP is frequently used to assess LV filling status, diagnose the severity of LV failure and quantify the severity of mitral stenosis, there are situations where PAOP correlates poorly with LVEDP (see Table 24.6).

Table 24.6

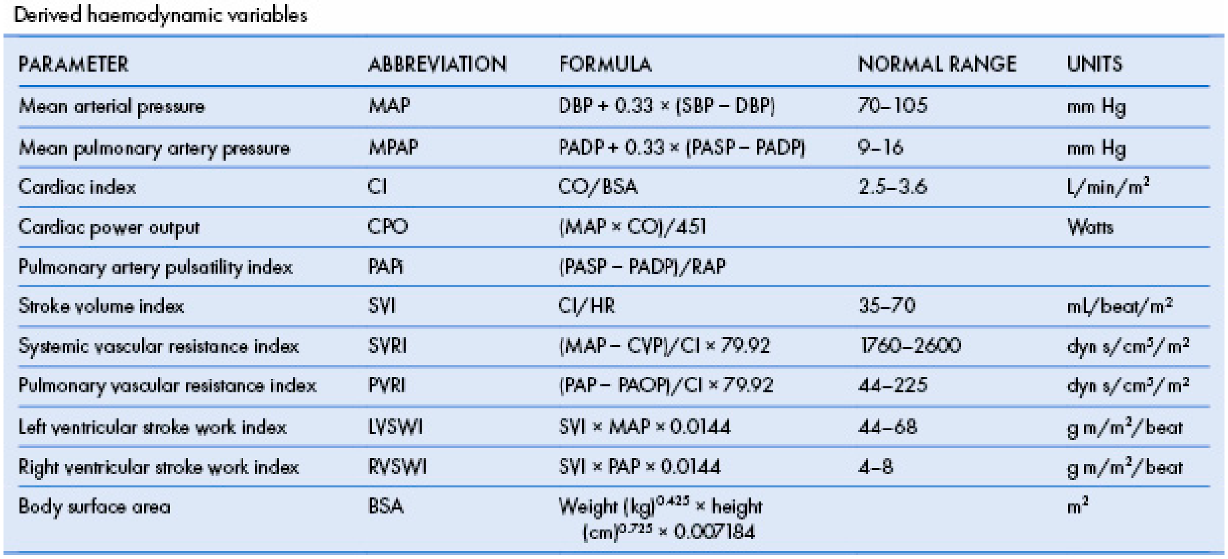
Potential Substitutes for Pulmonary Artery Occlusion Pressure (PAOP)

Measurement of PAOP requires wedging, which is associated with multiple risks including pulmonary infarction and pulmonary artery rupture. The normal pulmonary artery diastolic pressure (PADP) to PAOP gradient is less than 5 mm Hg, so that PADP may substitute as a close approximation for PAOP. However, tachycardia (>120/min) and conditions that increase pulmonary vascular resistance (such as ARDS, COPD and PE) variably alter this gradient, invalidating the direct substitution of PADP for PAOP. The relationship between PADP and PAOP tends to be stable over hours, allowing PADP to be monitored in the short term without repeated wedge manoeuvres. Echocardiographic assessment of fluid status is an increasingly common substitute for PAOP in critically ill patients and is discussed further in Chapter 25 .

Derived Variables

Many variables can be derived from the measurements obtained with a standard PAC, as outlined in Table 24.7 . PAPI and CPO are derived variables that provide information on ventricular function and are being investigated for their ability to guide therapies, including mechanical support and predict mortality in patients with cardiogenic shock.[52], [53]

Table 24.7



Derived haemodynamic variables

PARAMETER	ABBREVIATION	FORMULA	NORMAL RANGE	UNITS
Mean arterial pressure	MAP	DBP + 0.33 × (SBP – DBP)	70–105	mm Hg
Mean pulmonary artery pressure	MPAP	PADP + 0.33 × (PASP – PADP)	9–16	mm Hg
Cardiac index	CI	CO/BSA	2.5–3.6	$L/min/m^2$
Cardiac power output	CPO	(MAP × CO)/451		Watts
Pulmonary artery pulsatility index	PAPi	(PASP – PADP)/RAP		
Stroke volume index	SVI	CI/HR	35–70	$mL/beat/m^2$
Systemic vascular resistance index	SVRI	(MAP – CVP)/CI × 79.92	1760–2600	$dyn\ s/cm^5/m^2$
Pulmonary vascular resistance index	PVRI	(PAP – PAOP)/CI × 79.92	44–225	$dyn\ s/cm^5/m^2$
Left ventricular stroke work index	LVSWI	SVI × MAP × 0.0144	44–68	$g\ m/m^2/beat$
Right ventricular stroke work index	RVSWI	SVI × PAP × 0.0144	4–8	$g\ m/m^2/beat$
Body surface area	BSA	Weight $(kg)^{0.425}$ × height $(cm)^{0.725}$ × 0.007184		m^2

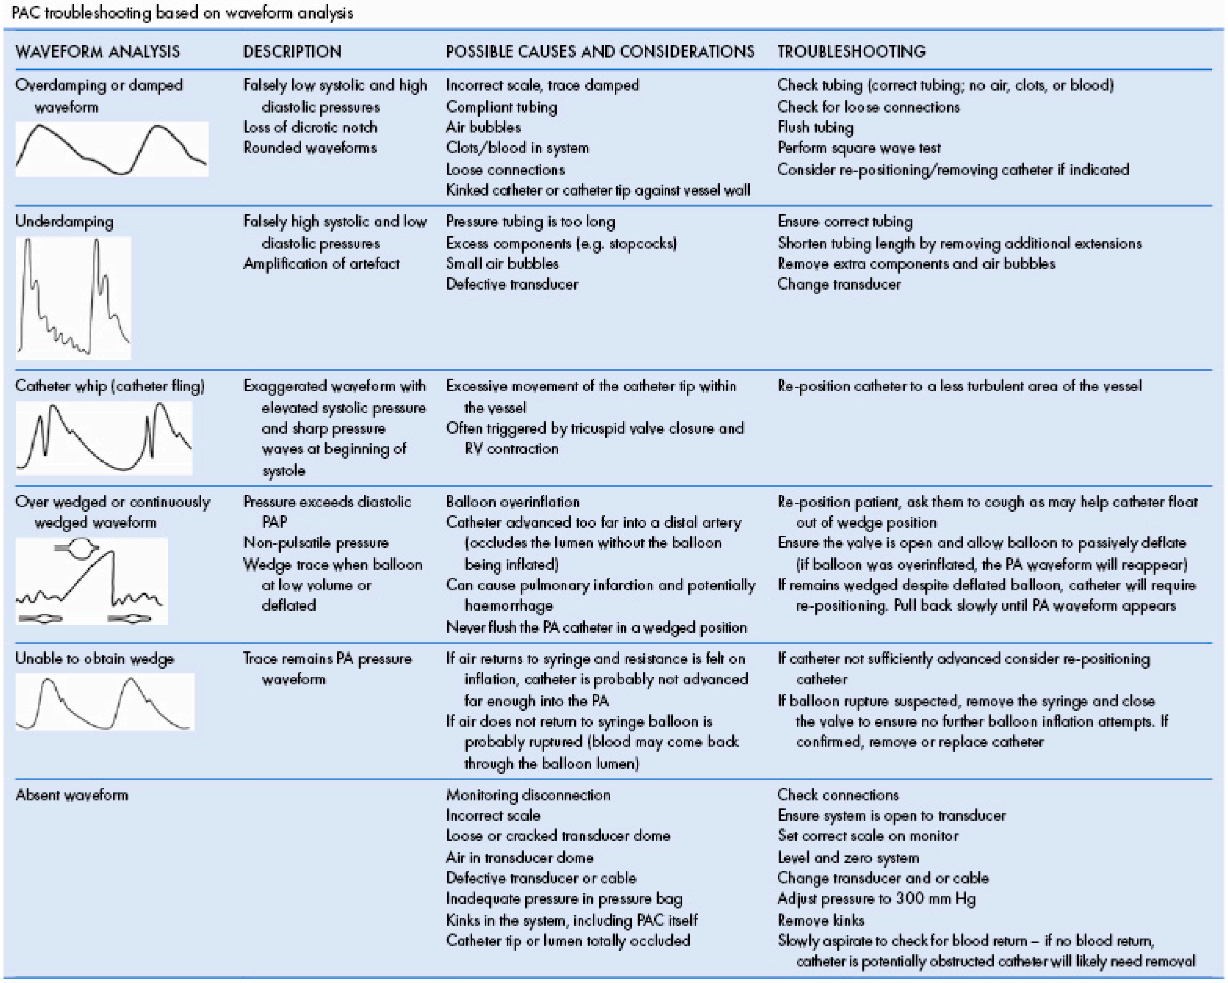
Mixed Venous Oxygen Tension and Saturation

These variables are discussed in Chapter 38 .

Troubleshooting the PAC

PAC waveform abnormalities may indicate problems with the function of the PAC. Troubleshooting approaches are outlined in Table 24.8 .

Table 24.8



PAC troubleshooting based on waveform analysis

WAVEFORM ANALYSIS	DESCRIPTION	POSSIBLE CAUSES AND CONSIDERATIONS	TROUBLESHOOTING
Overdamping or damped waveform	Falsely low systolic and high diastolic pressures Loss of dicrotic notch Rounded waveforms	Incorrect scale, trace damped Compliant tubing Air bubbles Clots/blood in system Loose connections Kinked catheter or catheter tip against vessel wall	Check tubing (correct tubing; no air, clots, or blood) Check for loose connections Flush tubing Perform square wave test Consider re-positioning/removing catheter if indicated
Underdamping	Falsely high systolic and low diastolic pressures Amplification of artefact	Pressure tubing is too long Excess components (e.g. stopcocks) Small air bubbles Defective transducer	Ensure correct tubing Shorten tubing length by removing additional extensions Remove extra components and air bubbles Change transducer
Catheter whip (catheter fling)	Exaggerated waveform with elevated systolic pressure and sharp pressure waves at beginning of systole	Excessive movement of the catheter tip within the vessel Often triggered by tricuspid valve closure and RV contraction	Re-position catheter to a less turbulent area of the vessel
Over wedged or continuously wedged waveform	Pressure exceeds diastolic PAP Non-pulsatile pressure Wedge trace when balloon at low volume or deflated	Balloon overinflation Catheter advanced too far into a distal artery (occludes the lumen without the balloon being inflated) Can cause pulmonary infarction and potentially haemorrhage Never flush the PA catheter in a wedged position	Re-position patient, ask them to cough as may help catheter float out of wedge position Ensure the valve is open and allow balloon to passively deflate (if balloon was overinflated, the PA waveform will reappear) If remains wedged despite deflated balloon, catheter will require re-positioning. Pull back slowly until PA waveform appears
Unable to obtain wedge	Trace remains PA pressure waveform	If air returns to syringe and resistance is felt on inflation, catheter is probably not advanced far enough into the PA If air does not return to syringe balloon is probably ruptured (blood may come back through the balloon lumen)	If catheter not sufficiently advanced consider re-positioning catheter If balloon rupture suspected, remove the syringe and close the valve to ensure no further balloon inflation attempts. If confirmed, remove or replace catheter
Absent waveform		Monitoring disconnection Incorrect scale Loose or cracked transducer dome Air in transducer dome Defective transducer or cable Inadequate pressure in pressure bag Kinks in the system, including PAC itself Catheter tip or lumen totally occluded	Check connections Ensure system is open to transducer Set correct scale on monitor Level and zero system Change transducer and or cable Adjust pressure to 300 mm Hg Remove kinks Slowly aspirate to check for blood return – if no blood return, catheter is potentially obstructed catheter will likely need removal

Cardiac Output Monitoring

CO monitoring is important as CO cannot be reliably measured by routine clinical assessment. Complications of PAC insertion and errors in data interpretation have driven the development of numerous commercially available devices.[1] These are non- or minimally invasive, and are based on the Fick principle, thermodilution, pulse contour analysis, Doppler or bioimpedance. These newer techniques[54] are discussed below.

Application of the Fick Principle

The Fick principle is an extension of the law of conservation of mass and states that the total uptake of a substance by an organ (or whole body), is equal to the product of the blood flow to the organ (or whole body), and the arteriovenous concentration difference (gradient) of the substance. Rearranged this gives us the equation:

$$CO = \frac{\dot{V}O_2}{C_a - C_v}$$

where $\overset{O_2}{V}$ is the oxygen consumption in mL/min and C_a and C_v are the arterial and venous oxygen content in ml/L.

A wide variety of techniques used to measure CO are based on this principle. The substance measured varies according to the technique being employed and includes oxygen (direct Fick method), carbon dioxide (indirect Fick method) or an indicator (thermal energy or lithium) dilution method.

The Direct Fick Method

The direct Fick method uses oxygen uptake from the lungs to determine the CO. Calculation of oxygen consumption ($\overset{O_2}{V}$) is performed by comparing the oxygen content of inhaled and exhaled gas. Arteriovenous concentration difference ($C_a - C_v$) is calculated by measuring venous and arterial oxygen content using mixed venous (via a PAC), and arterial blood gas samples. In most ICU patients the strict preconditions for this technique are not met, rendering it both time consuming and inaccurate. Physiological limitations include both the increased oxygen consumption of inflamed lungs (e.g. ARDS or pneumonia) and the impact of intra-cardiac shunts on venous and arterial oxygen content. While the direct Fick method is the gold standard for measuring CO, its use is mainly confined to cardiac laboratories.

The Indirect Fick Method

The indirect Fick method is a modification of the direct Fick method using carbon dioxide uptake as the substance and estimating rather than measuring one or more of the variables. The partial CO_2 rebreathing technique can be used to measure C_vCO_2 without a PAC,[55] but it is unsuitable for non-intubated patients, not validated in chronic lung disease and many important assumptions are not met in critically ill patients. Another commonly estimated variable is carbon dioxide consumption ($\overset{\mathrm{C}}{\mathrm{V}}\mathrm{O}_2$), where population nomograms are used instead. These tend to be inaccurate in obese or metabolically abnormal patients (e.g. hypothermia, sepsis or burns) and the effect of critical illness on the assumed variables makes the indirect Fick method unsuitable for clinical application.

Invasive Methods of Cardiac Output Monitoring

Bolus Thermodilution Cardiac Output

Intermittent measurement of CO by bolus thermodilution using a PAC is the clinical reference standard by which newer techniques are assessed. Standard PACs use a fixed volume bolus of crystalloid at a known temperature (injectate) that is delivered into the venous circulation and transiently decreases the downstream blood temperature in the pulmonary artery. This change in temperature is monitored by a thermistor proximal to the balloon at the tip of the catheter. The magnitude and speed of the temperature drop is related to the CO according to the modified Stewart–Hamilton equation:

$$Q = \frac{V \times (T_b - T_i)K_1 \times K_2}{Tb(t)\mathrm{d}t}$$

where Q is cardiac output, V is volume injected, T_b is blood temperature, T_i is injectate temperature, K_1 and K_2 are corrections for specific heat and density of injectate and for blood and dead space volumes and $Tb(t)\mathrm{d}t$ is change in blood temperature as a function of time.

Continuous Thermodilution Cardiac Output

Due to the known limitations of intermittent bolus CO measurement (see Table 24.9), methods to provide continuous cardiac output (CCO) monitoring have been developed.[56] These use a thermal filament wrapped around the RV segment of the catheter 15 to 25 cm from the tip. The filament heats up the adjacent blood in a random on-off pattern which is detected by the downstream thermistor. The changes in heat are used to generate a waveform and produce a CO value averaged over the previous 4 to 12 minutes. The signals are cross-correlated to allow differentiation of thermal signals from background thermal noise within the PAC. The CCO is more accurate than the bolus thermodilution method as it is independent of the user and not affected by injection technique or injectate volume. It also provides continuous monitoring of other values including SV, systemic vascular resistance (SVR) and mixed venous oxygen saturations. Incorporation of a rapid response thermistor into some PACs allows estimation of RV ejection fraction (RVEF) and RVEDV. However, CCO monitoring is not without drawbacks (see Box 24.5).

Table 24.9

Causes of inaccurate bolus thermodilution cardiac output measurements [57]

OVERESTIMATE OF CO	UNDERESTIMATE OF CO	VARIABLE EFFECT ON CO
Due to a smaller area under the thermodilution curve	Frequently in high-flow states where rapid temperature changes occur	Poor technique
Intra-cardiac shunts (left-to-right, or right-to-left)	Tricuspid regurgitation	Abnormal respiratory pattern
Small injectate volume	High injectate volume	Measurements at different points in the respiratory cycle
Higher injectate temperature compared with reference	High CO states	Cardiac dysrhythmias
Very low CO state	Slow injection (>4 seconds)	Catheter malposition
	Rapid intravenous infusions, especially if administered via the introducer sheath	Injectate port close to or within introducer sheath

Box 24.5

Potential drawbacks of continuous cardiac output (CCO) monitoring

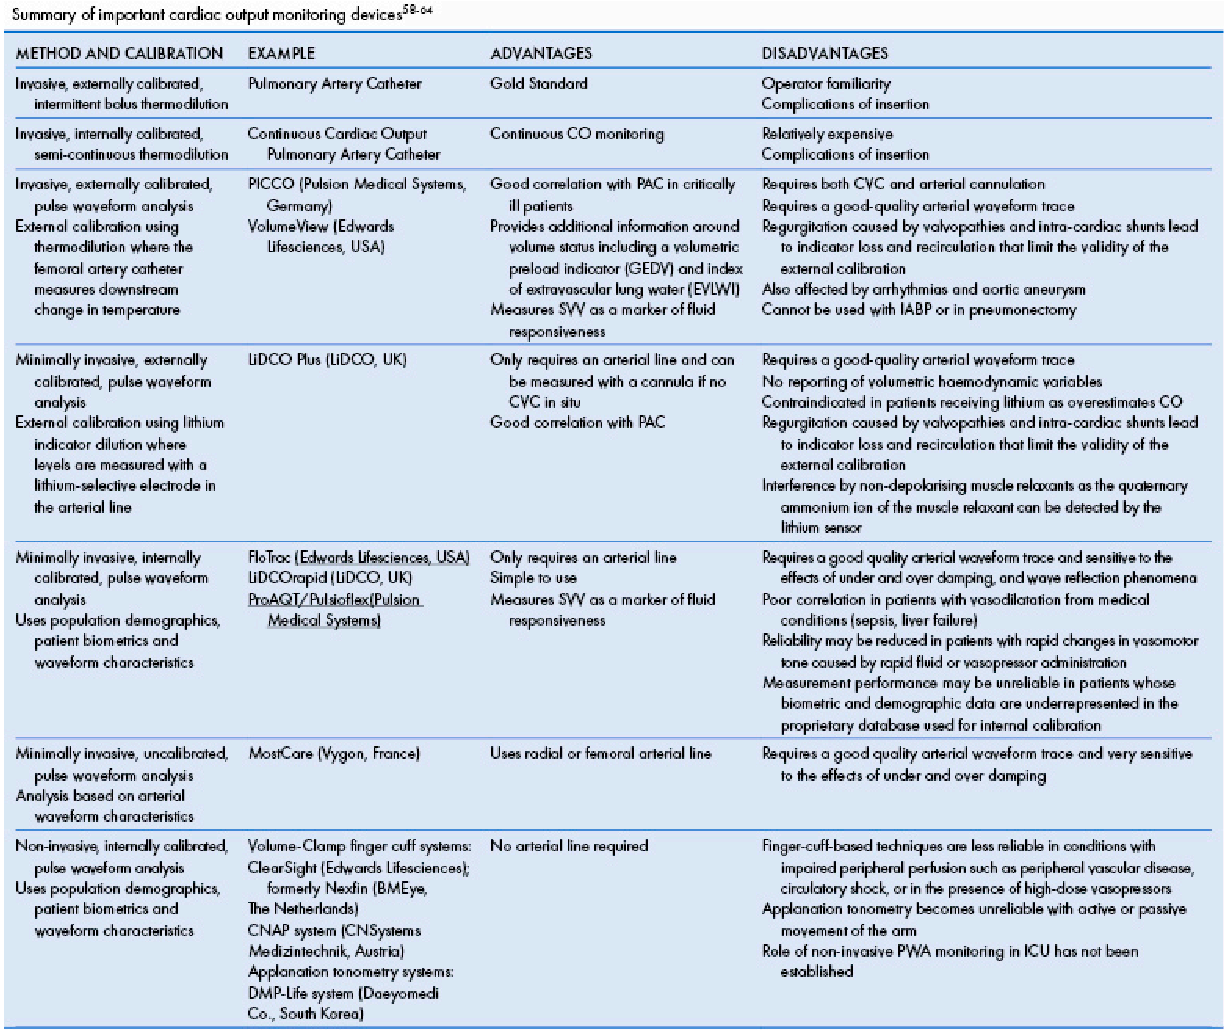
Inaccuracy during thermal disequilibrium, such as rapid infusions of cool fluids or after cardiac bypass
Delay in detecting sudden changes in CO as the CCO averages the values over time
Intra-cardiac shunts and tricuspid regurgitation will affect both bolus CO and CCO, but monitoring of trends in CO over time may still be useful
Magnetic resonance imaging is contraindicated as it can melt the thermal filament
Electro-cautery can interfere with measurements

Minimally Invasive Methods

Transpulmonary Indicator Dilution

These devices use the same basic principles of thermodilution as the PAC to estimate CO. Thermal (cold intravenous fluid) or other indicators (e.g. lithium) are injected via a central vein and the changes in temperature or concentration are detected in a systemic artery. As the indicators pass through all chambers of the heart and the entire pulmonary circulation, central blood volumes and indices of extravascular lung water can also be quantified. There are multiple devices using transpulmonary indicator dilution on the market, and they use proprietary technology and algorithms to measure CO and calculate derived variables (see Table 24.10).

Table 24.10



Summary of important cardiac output monitoring devices[58-64]

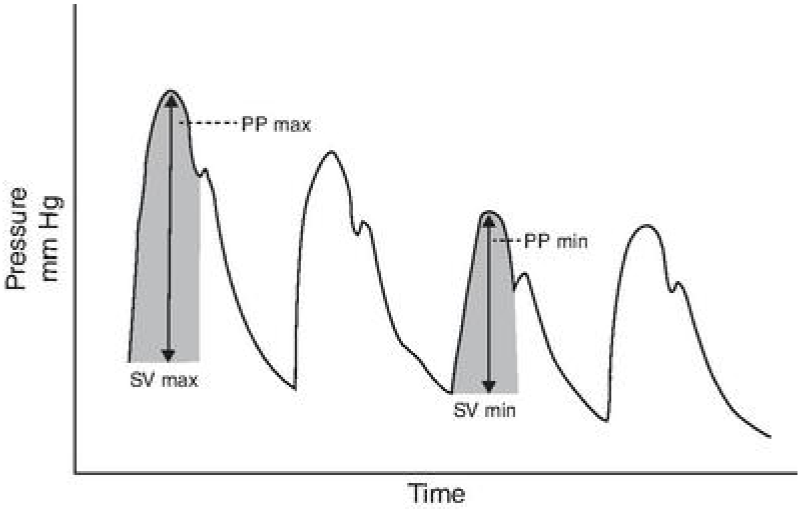
METHOD AND CALIBRATION	EXAMPLE	ADVANTAGES	DISADVANTAGES
Invasive, externally calibrated, intermittent bolus thermodilution	Pulmonary Artery Catheter	Gold Standard	Operator familiarity Complications of insertion
Invasive, internally calibrated, semi-continuous thermodilution	Continuous Cardiac Output Pulmonary Artery Catheter	Continuous CO monitoring	Relatively expensive Complications of insertion
Invasive, externally calibrated, pulse waveform analysis External calibration using thermodilution where the femoral artery catheter measures downstream change in temperature	PICCO (Pulsion Medical Systems, Germany) VolumeView (Edwards Lifesciences, USA)	Good correlation with PAC in critically ill patients Provides additional information around volume status including a volumetric preload indicator (GEDV) and index of extravascular lung water (EVLWI) Measures SVV as a marker of fluid responsiveness	Requires both CVC and arterial cannulation Requires a good-quality arterial waveform trace Regurgitation caused by valvopathies and intra-cardiac shunts lead to indicator loss and recirculation that limit the validity of the external calibration Also affected by arrhythmias and aortic aneurysm Cannot be used with IABP or in pneumonectomy
Minimally invasive, externally calibrated, pulse waveform analysis External calibration using lithium indicator dilution where levels are measured with a lithium-selective electrode in the arterial line	LiDCO Plus (LiDCO, UK)	Only requires an arterial line and can be measured with a cannula if no CVC in situ Good correlation with PAC	Requires a good-quality arterial waveform trace No reporting of volumetric haemodynamic variables Contraindicated in patients receiving lithium as overestimates CO Regurgitation caused by valvopathies and intra-cardiac shunts lead to indicator loss and recirculation that limit the validity of the external calibration Interference by non-depolarising muscle relaxants as the quaternary ammonium ion of the muscle relaxant can be detected by the lithium sensor
Minimally invasive, internally calibrated, pulse waveform analysis Uses population demographics, patient biometrics and waveform characteristics	FloTrac (Edwards Lifesciences, USA) LiDCOrapid (LiDCO, UK) ProAQT/Pulsioflex(Pulsion Medical Systems)	Only requires an arterial line Simple to use Measures SVV as a marker of fluid responsiveness	Requires a good quality arterial waveform trace and sensitive to the effects of under and over damping, and wave reflection phenomena Poor correlation in patients with vasodilatation from medical conditions (sepsis, liver failure) Reliability may be reduced in patients with rapid changes in vasomotor tone caused by rapid fluid or vasopressor administration Measurement performance may be unreliable in patients whose biometric and demographic data are underrepresented in the proprietary database used for internal calibration
Minimally invasive, uncalibrated, pulse waveform analysis Analysis based on arterial waveform characteristics	MostCare (Vygon, France)	Uses radial or femoral arterial line	Requires a good quality arterial waveform trace and very sensitive to the effects of under and over damping
Non-invasive, internally calibrated, pulse waveform analysis Uses population demographics, patient biometrics and waveform characteristics	Volume-Clamp finger cuff systems: ClearSight (Edwards Lifesciences); formerly Nexfin (BMEye, The Netherlands) CNAP system (CNSystems Medizintechnik, Austria) Applanation tonometry systems: DMP-Life system (Daeyomedi Co., South Korea)	No arterial line required	Finger-cuff-based techniques are less reliable in conditions with impaired peripheral perfusion such as peripheral vascular disease, circulatory shock, or in the presence of high-dose vasopressors Applanation tonometry becomes unreliable with active or passive movement of the arm Role of non-invasive PWA monitoring in ICU has not been established

Arterial Pressure Waveform Analysis

Numerous devices use pulse wave (contour) analysis (PWA) to estimate real-time, continuous CO and to provide a dynamic assessment of preload variables predictive of fluid responsiveness such as PPV and SVV. SV and CO are calculated by mathematical algorithms based on a predictable relationship between the SV ejected from the LV and the area under the systolic component of the arterial pressure waveform. [65]

However, as described previously, the arterial pressure waveform is derived from complex signals and is determined by the interaction of many physiological factors that can affect the accuracy and precision of PWA devices.

Positive pressure ventilation increases intra-thoracic pressure during lung inflation, causing an increase in RAP, decreased VR and decreased RV preload. The resultant fall in RV SV leads to decreased LV SV and CO a few heartbeats later. The SV and PP fluctuations observed with ventilation are more marked when the filling status is on the ‘steep slope’ of the Frank-Starling curve. The variation in PP and SV with ventilation can be expressed as the PPV (Fig. 24.6) and SVV. The PPV appears more reliable for predicting fluid responsiveness.[66,67] For patients in sinus rhythm who are mechanically ventilated with tidal volumes >8 mL/kg predicted body weight a PPV >12.5% has an area under the receiver operator curve (AUROC) of 0.94 for predicting fluid responsiveness[68] (see Chapter 9).



The pressure waveform graph presents pressure on the vertical axis in millimetres of mercury and time on the horizontal axis. A series of arterial pressure waveforms is plotted as a repeating curve with peaks and troughs. Two cycles are highlighted with shaded areas. The first shaded waveform is labelled S V max and P P max, with arrows depicting the maximum stroke volume and maximum pulse pressure. The second shaded waveform is labelled S V min and P P min, with arrows pointing to the minimum stroke volume and minimum pulse pressure. The height between the peak and trough of each shaded area represents the pulse pressure amplitude. The diagram visually contrasts the hemodynamic differences between maximum and minimum values of stroke volume and pulse pressure within the cardiac cycle.

FIG. 24.6 Calculation of pulse pressure variation (PPV) and stroke volume variation (SVV) using the arterial waveform. Maximum and minimum values for pulse pressure (PPmax; PPmin) and stroke volume (SVmax; SVmin) are derived from the arterial pressure waveform. The PPV and SVV are then calculated using the

equations: PPV = (PPmax – PPmin) / ((PPmax + PPmin)/2) and SVV = (SVmax – SVmin) / ((SVmax + SVmin)/2).

PWA methods for determining CO are classified in terms of invasiveness (invasive, minimally invasive or non-invasive) and by their method of calibration (externally calibrated, internally calibrated or uncalibrated) (see Table 24.10). The calibration and limitations of individual devices have been comprehensively described in recent reviews. [65, 69]

The decision to use PWA systems depends on the clinical applicability of the information provided, institutional preference and availability and the experience of the treating clinician. Current data suggest that PWA devices produce CO data that may be useful for goal-directed therapy in peri-operative settings, such as high-risk patients undergoing major abdominal surgery, though research is ongoing. [70]

All commercially available PWA systems that estimate CO have been compared in small studies to PAC or other transpulmonary thermodilution methods. The significant heterogeneity of study design, and the lack of agreed standards for these PWA devices, has generated conflicting data on the accuracy and precision of these devices. Pooled data suggest that these devices cannot be relied on to continuously and accurately measure CO in intensive care settings due to unacceptable percentage error rates. [65, 71, 72]

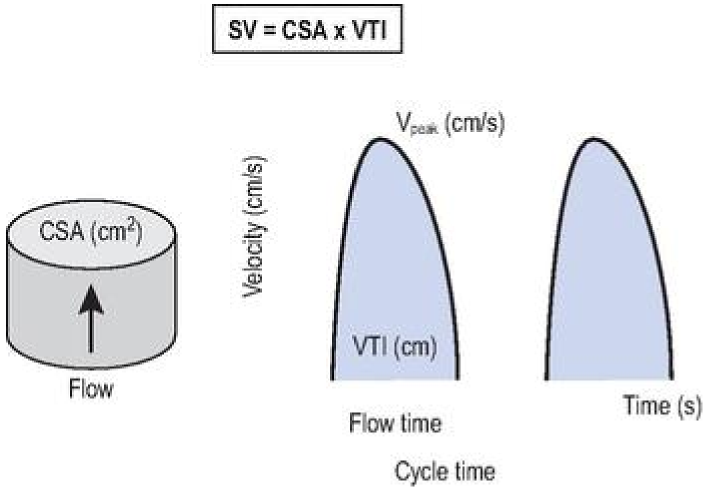
Non-Invasive Methods

Ultrasound

Ultrasound is increasingly used to evaluate critically ill patients as part of the trend towards less invasive, qualitative, discontinuous and functional monitoring. [73] It frequently complements other monitoring approaches. Inferior vena cava (IVC) and SVC diameter can be used as imperfect surrogates for CVP and preload. [74] Whole body ultrasound approaches (e.g. RUSH and eFAST in trauma) that include lung, pleura, abdominal and/or deep vein thrombosis ultrasound are diagnostically useful in haemodynamically unstable patients. [75, 76] Quantification of venous congestion can guide therapy, and is evaluated using the VExUS grading system which combines measurement of IVC diameter with venous

Doppler waveforms of the portal, hepatic and interlobular renal veins.[77] Additionally, echocardiography provides useful diagnostic information, including regional wall motion abnormalities, valvular abnormalities and paradoxical septal motion.

There are two main ultrasound approaches used to assess CO: (1) echocardiographic changes in ventricular volume and (2) Doppler measurement. Of note, LV outflow tract (LVOT) velocity-time integral (VTI) is widely used in critical care echocardiography to estimate CO. LVOT VTI is the distance the blood travels across the LVOT with each heartbeat and is calculated from tracing the LVOT pulsed wave doppler (PWD) spectral display. It is based on the Doppler principle (described below) and its calculation is shown in Fig. 24.7 . Sonographic methods of CO monitoring are outlined in Table 24.11 and the role of echocardiography in critical care is discussed further in Chapter 25 .



The diagram presents a conceptual formula and illustrations related to stroke volume measurement. At the top centre, the formula S V equals C S A multiplied by V T I is displayed. On the left, a cylindrical vessel is shown with upward flow and labelled C S A in square centimetre, representing cross-sectional area. To the right, two velocity waveforms are displayed. The first waveform is a triangular-shaped curve labelled velocity in centimetre per second on the vertical axis and cycle time on the horizontal axis. The curve has a peak labelled V peak and an area beneath the curve shaded and labelled V T I in centimetres. The second waveform is similarly shaped, showing time in seconds on the horizontal axis and velocity on the vertical axis without additional labels. The components collectively illustrate the relationship between flow velocity, cross-sectional area, and time integrated velocity in quantifying stroke volume.

FIG. 24.7 Doppler stroke volume (SV) calculation. The cross-sectional area (CSA) of flow is calculated as a circle from ultrasound measurements or nomogram-based estimations. Velocity-time integral (VTI) is the integral of Doppler velocity with regard to time.

SV is the product of CSA and VTI (mL/s in this example). Cardiac output is the product of SV and heart rate. Peak velocity of flow (V_{peak}) is also shown.

Table 24.11

The Doppler Principle

The Doppler principle states that the frequency of reflected sound is altered by a moving target, such as red blood cells (RBCs). [78] Doppler shift is determined by three variables: ultrasound probe frequency (high frequencies sacrifice penetrance for greater sensitivity to flow), blood velocity (greater Doppler shift at higher velocities) and the angle of insonance (the angle between the incident beam and the vector of blood flow). Continuous wave (CW) and pulsed wave (PW) Doppler are the main techniques employed to measure flow. PW Doppler is less accurate at high velocities whereas continuous Doppler lacks depth discrimination. PW Doppler cyclically transmits a pulse of sound energy and then pauses to receive the reflected signal from the specified location. With CW Doppler, a piezoelectric crystal transmits the ultrasound beam continuously, while another measures the frequency of reflected waves. The velocities of the RBCs moving along the path of the ultrasound beam are recorded as a 'Doppler envelope', with the outer border corresponding to the fastest-moving RBCs. The flow velocity of RBCs can be determined from the Doppler shift in the frequency of reflected waves (see Chapter 25). The most accurate results are obtained when the ultrasound beam is parallel to flow, however, angles up to 20 degree still yield acceptable results.

This methodology forms the basis of numerous monitoring devices (see Table 24.11). Advantages of Doppler, in general, include less dependence on image quality, good agreement with thermodilution and good reproducibility.

Thoracic Electrical Bioimpedance and Bioreactance

Thoracic electrical bioimpedance and bioreactance are appealing methods as they allow truly non-invasive and continuous estimation of CO. [86]

However, their limitations preclude clinical application at present. They are described in Table 24.12 .

Table 24.12

Functional Haemodynamic Monitoring

Functional haemodynamic monitoring assesses physiological reserve by observing the response to a physiological stimulus or stressor. [87] The main area of interest is in determining fluid responsiveness (also termed preload or volume responsiveness), which is variably defined as an increase in CO by 10%–15% after intravenous fluid loading with a 500 mL bolus over 10–15 minutes. The objective is to guide adequate fluid resuscitation while avoiding excessive fluid administration, which risks tissue and pulmonary oedema with consequent issues such as respiratory dysfunction, impaired wound healing, intrabdominal hypertension and worse patient outcomes. [88] Furthermore, only half of patients with shock show improvement in BP or CO with the administration of fluids, [89] so identification of potential ‘responders’ prior to a fluid challenge is important. Numerous ‘static’ and ‘dynamic’ measures have been studied for this purpose. However, as mentioned in the discussion of CVP, ‘static’ measures – except at their extremes – are not useful because they provide surrogates for preload rather than ‘preload responsiveness’. Of the ‘dynamic’ manoeuvres, amongst the most promising are the passive leg raise (PLR), tidal volume challenge (TVC) and end-expiratory occlusion test (EEOT) (see Table 24.13), but each has limitations. PLR is notable in that it can be performed in non-ventilated patients. These manoeuvres can be coupled with many of the CO monitoring approaches already described. PPV and SVV are often used but are only appropriate for patients who are in sinus rhythm. Many of the studies of fluid responsiveness have been performed in highly selected patients (e.g. mechanically ventilated and normal cardiac function), which may limit their generalisability to clinical practice. Ultimately, it must be remembered that being ‘fluid responsive’ does not mean fluid administration will actually benefit the patient.

Table 24.13

Common dynamic manoeuvres for assessing preload responsiveness [90]

DYNAMIC MANOEUVRE	TECHNIQUE	LIMITATIONS
Passive leg raise (PLR)	Sit patient at 45 degrees head up semi-recumbent position by adjusting the bed Lower patient’s upper body to horizontal and passively raise legs at 45 degrees up by adjusting the bed Maximal effect occurs at 30–90 seconds, and should then return to baseline	Unreliable in hypovolaemia and intrabdominal hypertension Need to pause other interventions during the test Positional changes may be contraindicated in some patients (e.g. raised intracranial pressure)
Tidal volume challenge (TVC)	Perform controlled ventilation with tidal volume >8 mL/kg PBW	Can only be used in mechanically ventilated patients Less sensitive if poor lung compliance (e.g. ARDS) Unreliable if spontaneous breathing, or intra-abdominal hypertension
End-expiratory occlusion test	Perform end-expiratory hold for	Requires precise and real-time CO measurement

DYNAMIC MANOEUVRE	**TECHNIQUE**	**LIMITATIONS**
(EEOT)	15 seconds Response only lasts seconds	Can only be used in mechanically ventilated patients. Less sensitive if poor lung compliance (e.g. ARDS) Unreliable if spontaneous breathing, proning or intra-abdominal hypertension

Monitoring the Microcirculation

Microcirculatory dysfunction is present in many critical illnesses, particularly sepsis, and likely contributes to organ dysfunction and poor outcomes.[91], [92] It manifests as blood flow abnormalities and a decreased density of perfused vessels. In critical illness, microvascular perfusion at the level of the arterioles, capillaries and venules often lacks coherence with systemic arterial pressure and CO. However, microvascular pathologies may be heterogeneous (e.g. variably affecting the skin or other organs), in which case monitoring a local microcirculation may not offer generalisable data. Evaluation of the microcirculation in clinical practice remains problematic.

A wide range of techniques have been used in research to assess the microcirculation.[91], [92] These include clinical examination, direct visualisation and indirect measures. Clinically, mottled skin, acrocyanosis, delayed capillary refill time (CRT) and increased central to peripheral temperature gradients may indicate an impaired microcirculation, but lack specificity. Encouragingly, the ANDROMEDA-SHOCK trial used CRT as part of a microcirculation-guided strategy for treating septic shock and outcomes compared favourably with a lactate-guided strategy.[93] Direct visualisation of superficial capillary beds can be performed using nailfold videocapillaroscopy and hand-held vital microscopy (HVM) of the sublingual microcirculation. Indirect measures include laser Doppler flowmetry, contrast-enhanced ultrasound, near-infrared spectroscopy (NIRS) and assessing the veno-arterial PCO_2 gap ($P_{v-a}CO_2$ gap). The $P_{v-a}CO_2$ gap can be performed using existing bedside sampling methods and indicates impaired tissue perfusion, whether due to global CO or impaired microcirculation.[94] This is because CO_2 is highly soluble and diffuses into the venous effluent even in situations where an O_2 diffusion barrier exists (e.g. non-functional capillaries), which may prevent oxygen extraction and mask local tissue oxygen debt. Limitations are that it does not indicate tissue dysoxia and there is a lack of studies demonstrating an impact on outcomes of shock states through measurement of the $P_{v-a}CO_2$ gap. Assessment of the microcirculation is further discussed in Chapter 38 .

Echocardiography in intensive care

James Richards Anstey, Craig George Terrell Morris and Ubbo F. Wiersema

Ultrasound Physics

Ultrasound consists of waves of alternating compression and rarefaction at frequencies higher than those audible to the human ear (approx. 20 kHz). Ultrasound imaging involves the transmission and subsequent detection of the returning waves, reflected at interfaces between tissues with differing acoustic impedance. The depth of the reflecting interface is determined by the time taken for the pulse of ultrasound waves to return, assuming a constant velocity of transmission through tissues (1540 m/s).

For transthoracic echocardiography (TTE), ultrasound frequencies of 1–5 MHz are used, which is a compromise between the higher spatial resolution achieved at higher frequencies and the greater depth penetration achieved with lower-frequency imaging. A transoesophageal echocardiography (TOE) ultrasound transducer uses higher frequencies (3–7 MHz) and is closer to insonated structures, allowing superior definition.

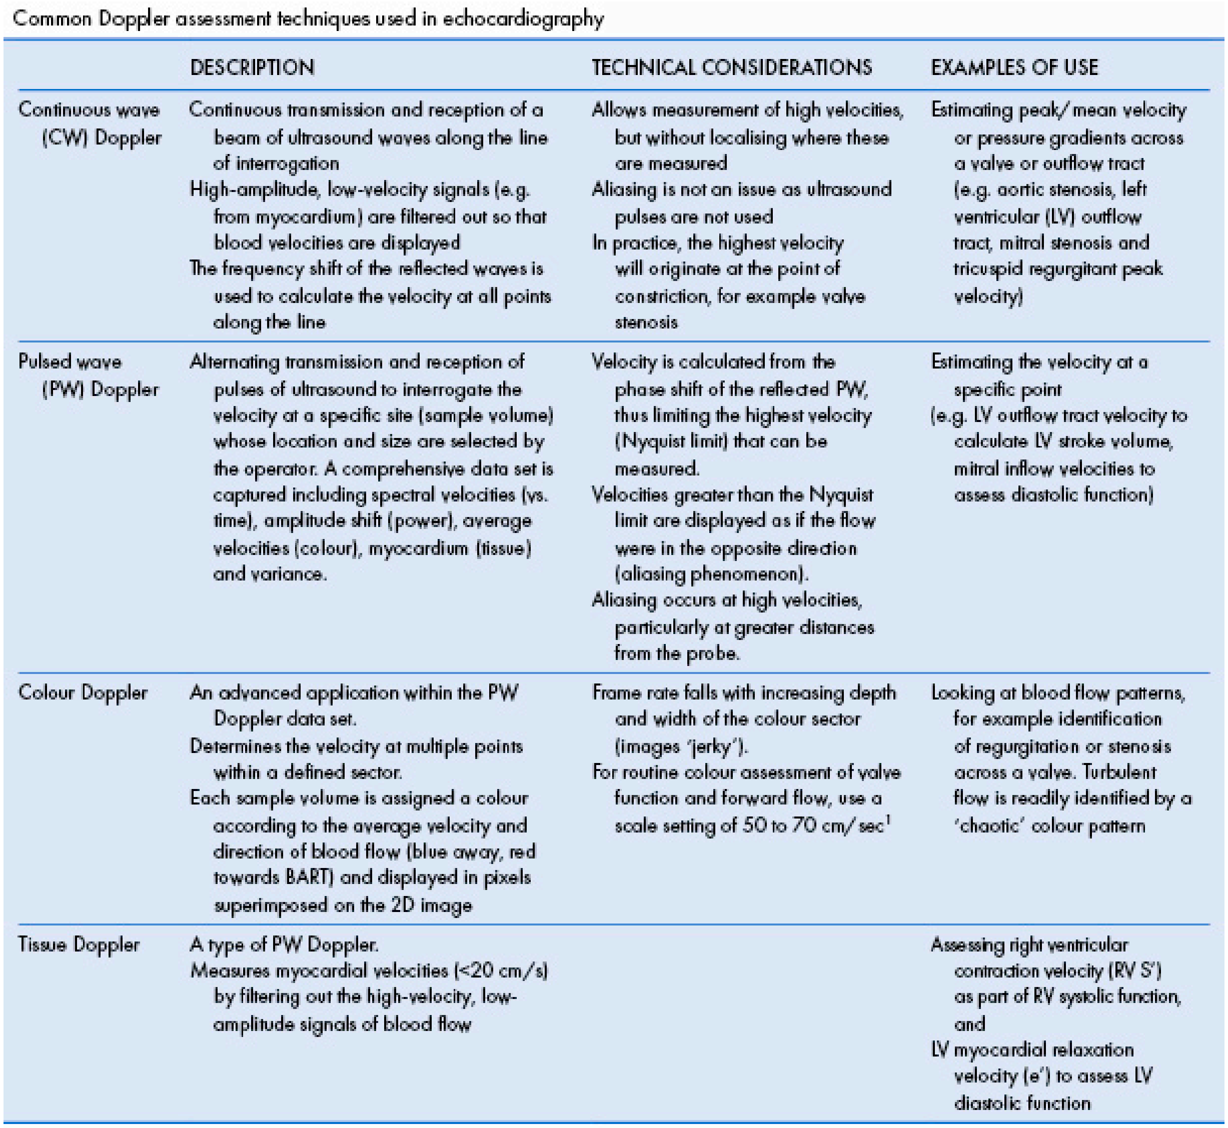
To build a 2D image, the ultrasound beam is electronically swept across the plane of interrogation exploiting wave phase interference, hence the name ‘phased array probe’. The frame rate is the frequency with which the 2D image is renewed (temporal resolution), which depends on the pulse repetition frequency and the image width (number of scan lines). Newer-generation probes allow the 3D representation of structures by compounding voxels (3-D equivalent of 2-D pixels) of volumetric data, but this requires good-quality images captured over several cardiac cycles.

Doppler Echocardiography

The Doppler effect is the change in frequency (Δf) of ultrasound waves that occurs when the reflecting body is moving relative to the wave transmitter and receiver. The velocity of the body (v) can be calculated from the measured frequency shift by the Doppler equation: $v = c(\Delta f)/2f_T .\cos\theta$ where c is the velocity of sound in soft tissue (1540 m/s), f_T is the transmitted frequency and θ is the angle between the ultrasound beam and the direction of movement. The $\cos\theta$ relationship means Doppler interrogation at angles significantly more than 20–30 degrees off parallel with flow underestimate velocity, while Doppler ultrasound at 90 degrees to flow shows no Doppler shift.

The four most commonly used modes of Doppler echocardiography are summarised in Table 25.1 .

Table 25.1



Common Doppler assessment techniques used in echocardiography

	DESCRIPTION	TECHNICAL CONSIDERATIONS	EXAMPLES OF USE
Continuous wave (CW) Doppler	Continuous transmission and reception of a beam of ultrasound waves along the line of interrogation High-amplitude, low-velocity signals (e.g. from myocardium) are filtered out so that blood velocities are displayed The frequency shift of the reflected waves is used to calculate the velocity at all points along the line	Allows measurement of high velocities, but without localising where these are measured Aliasing is not an issue as ultrasound pulses are not used In practice, the highest velocity will originate at the point of constriction, for example valve stenosis	Estimating peak/mean velocity or pressure gradients across a valve or outflow tract (e.g. aortic stenosis, left ventricular (LV) outflow tract, mitral stenosis and tricuspid regurgitant peak velocity)
Pulsed wave (PW) Doppler	Alternating transmission and reception of pulses of ultrasound to interrogate the velocity at a specific site (sample volume) whose location and size are selected by the operator. A comprehensive data set is captured including spectral velocities (vs. time), amplitude shift (power), average velocities (colour), myocardium (tissue) and variance.	Velocity is calculated from the phase shift of the reflected PW, thus limiting the highest velocity (Nyquist limit) that can be measured. Velocities greater than the Nyquist limit are displayed as if the flow were in the opposite direction (aliasing phenomenon). Aliasing occurs at high velocities, particularly at greater distances from the probe.	Estimating the velocity at a specific point (e.g. LV outflow tract velocity to calculate LV stroke volume, mitral inflow velocities to assess diastolic function)
Colour Doppler	An advanced application within the PW Doppler data set. Determines the velocity at multiple points within a defined sector. Each sample volume is assigned a colour according to the average velocity and direction of blood flow (blue away, red towards BART) and displayed in pixels superimposed on the 2D image	Frame rate falls with increasing depth and width of the colour sector (images 'jerky'). For routine colour assessment of valve function and forward flow, use a scale setting of 50 to 70 cm/sec[1]	Looking at blood flow patterns, for example identification of regurgitation or stenosis across a valve. Turbulent flow is readily identified by a 'chaotic' colour pattern
Tissue Doppler	A type of PW Doppler. Measures myocardial velocities (<20 cm/s) by filtering out the high-velocity, low-amplitude signals of blood flow		Assessing right ventricular contraction velocity (RV S') as part of RV systolic function, and LV myocardial relaxation velocity (e') to assess LV diastolic function

Measurement of blood velocity by Doppler methods converts a 2D imaging transducer into a device which can calculate blood flow and estimate pressure gradients.

- Volumetric flow is calculated from the velocity and the cross-sectional area of the structure through which the blood flows. Accuracy depends on parallel alignment of the Doppler ultrasound beam with flow, a laminar flow with a flat profile, and most crucially, accurate measurement of the cross-sectional area. For pulsatile flow, the stroke volume is calculated from the integral of instantaneous velocity with respect to time (velocity–time integral [VTI]), multiplied by the cross-sectional area).

The *continuity principle* states that the net volume of blood passing through one part of the heart equals the volume passing through another part of the heart, provided that there is no shunt.

The *principle of conservation of energy* allows pressure gradients (ΔP) across valves and between chambers to be estimated from velocity, using the Bernoulli equation.

In practice, a simplified form of the Bernoulli equation is mostly used, $\Delta P = 4v^2$, where pressure is in mmHg and velocity is in m/s. This underestimates the pressure gradient when the maximum velocity is not identified, and overestimates pressure gradients if the proximal velocity is greater than 1 m/s. Consequently, a non-invasive ultrasound transducer applying Doppler technology can derive 2-D images, pressures and flows and has replaced routine invasive catheter studies (e.g. assessing aortic stenosis or pulmonary artery catheterisation).

Artefacts

Imaging artefacts can result in false, missing or distorted structures. Failure to recognise artefacts may lead to misinterpretation and misdiagnosis. Artefacts may occur with 2D and Doppler imaging. Prosthetic devices such as catheters, wires and prosthetic valves are particularly prone to causing artefacts. Decreasing the gain, adjustment of focal depth and alternative imaging planes and using colour Doppler can help distinguish between artefacts and true structures.

Point-of-Care Ultrasound Versus Comprehensive Ultrasound

Terms such as point-of-care, emergency ultrasound and focused studies are used interchangeably and encompass a number of broad principles as distinct from a ‘comprehensive’ ultrasound (Table 25.2).

Table 25.2

Comparison of point-of-care ultrasound with comprehensive ultrasound

	POINT-OF-CARE ULTRASOUND	COMPREHENSIVE ULTRASOUND
Performed by	Clinician treating patient with access to clinical details/assessment	Visiting imaging specialist with a formal request
Nature of study	Directed to a clinically prompted question, which often has a ‘yes/no’ answer	A complete study which is summarised in a standard report
Time scale	Acute, as needed, and can be repeated	Within service constraints and at discretion of service provider
Governance	Clinicians need to be aware of diagnostic overreach and have access to specialist opinion and interpretation in complex cases.	Service provided by the hospital specialist
Training	Bespoke modular packages which may be merged e.g. echocardiography and lung/pleura, shock/periarrest protocols	Defined pathway, typically focusing on the organ of interest (e.g. cardiac)
Equipment	Three probes (linear, curvilinear and phased array) with breadth of applications across the body	Dedicated, high-specification machine

Components of Critical Care Echocardiography

For focused (transthoracic) cardiac ultrasound, 2D images are obtained from the parasternal long-axis (PLAX) view, parasternal short-axis (PSAX) mid-papillary view, apical four-chamber view and subcostal four-chamber and inferior vena cava (IVC) views and a typical point-of-care dataset comprises largely 2D imaging with minimal measurements. [1-3] For a more complete study, additional parasternal and apical views and Doppler methods are required. [4,5]

Left Ventricle

Echocardiographic evaluation of the left ventricle (LV) should assess LV size (dimension or volume), wall thickness and function; however, subjective estimation ('eyeballing') is often sufficient to guide clinical decision-making.

LV basal dimension, measured in 2D at end-diastole in the PLAX view, offers a rapid evaluation of LV size. LV wall thickness of the LV anteroseptal and basal inferolateral walls is measured in end-diastole in the PLAX view. A normal wall thickness is generally less than about 1.0 cm, and it is severely thickened if >1.6 cm. [6,7] Wall thickness as an estimate of LV mass relies on assumptions, including that the LV is of normal geometry.

LV systolic function consists of both radial (luminal or inward) and longitudinal contraction (base towards the apex) and it is important to assess movement *and* thickening. Parasternal short-axis views allow radial thickening of LV segments to be observed in the three coronary perfusion territories, at the three levels of the heart (base, mid and apex); in a limited study, the mid-papillary view alone provides rapid assessment. Normal LV wall thickening is greater than 30%. LV systolic function can be evaluated using fractional shortening (change in LV basal dimension), fractional area change (change in LV cross-sectional area) or ejection fraction (EF) (change in volume). Normal EF is greater than 55%; severe dysfunction is an EF less than 30%. The standard EF method in a cardiology setting is the

Simpson’s biplane method. In the critical care environment, this method is prone to inaccuracies from apical foreshortening, especially with mechanical ventilation, and poor endocardial definition. For experienced observers, visual assessment of the LVEF has been shown to agree well with measured EF by the Simpson’s biplane method.[6,7] Newer, automated analysis packages offer rapid, accurate estimates of LVEF collected over several cardiac cycles,[8,9] but require good image quality.

Regional LV systolic function is described for each wall segment by the extent of wall thickening and inward wall motion during systole. Regional abnormalities are usually due to coronary artery disease, although stress-induced (‘Takotsubo’) cardiomyopathy has a typical distribution of mid-to-apical LV hypokinesis with ‘ballooning’.

Context is important in the interpretation of LV systolic function because of the influence of loading conditions (preload and afterload) and the degree of cardiorespiratory support (inotropes, positive pressure ventilation). LVEF overestimates LV systolic function and cardiac output in the presence of significant mitral regurgitation and ventricular septal defect (VSD).

When evaluating cardiac function, estimating LV stroke volume using the LV outflow tract (LVOT) VTI, gives valuable information. This is measured with PW Doppler from the apical 5-chamber or 3-chamber view. In a dilated heart, the LVEF may be decreased, but the stroke volume may be relatively preserved. Importantly, the LVEF may be normal or high in some patients who actually have a low stroke volume (e.g. severe mitral regurgitation, hypovolemia, vasodilatation, RV failure and VSD). Assessing both the LVEF and the LVOT VTI avoids errors in interpretation from EF alone (Table 25.3).

Table 25.3

Right Ventricle

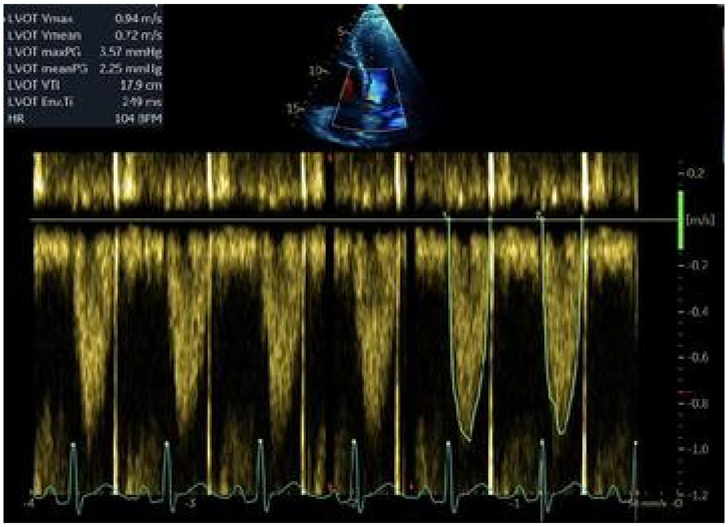
It is essential to assess the right ventricle (RV) in a critical care echocardiogram although its complex shape and mode of contraction make measurement of RV size from 2D images challenging. The RV may suffer primary insults (e.g. infarction), and being very thin walled, it is highly sensitive to changes in afterload (e.g. pulmonary embolus and lung or left heart pathology). RV size can be quickly assessed by comparing the RV cavity area to the LV cavity area (assuming LV is not dilated), from the apical 4-chamber window, taking care to avoid foreshortening (excessively medial position). As the RV dilates, it contributes progressively more to the cardiac apex than the LV.

RV-free wall thickness is measured at end-diastole by M-mode or 2D echocardiography in the subcostal four-chamber view or parasternal long-axis view, taking care to exclude trabeculation. An RV wall thickness greater than 4 mm signifies hypertrophy and implies chronicity.

Obtaining an RV-focused view is helpful in the assessment of RV systolic function and measuring its size. Subjective assessment of RV size and function by echo-trained ICU specialists has been found to be reliable,[8] but combining this with objective measures is recommended.

In contrast to the LV, normal RV contractility is approximately 75% longitudinal and 25% radial, although radial function becomes more representative of global RV function in states of increased RV afterload and hypertrophy.[11,12] Longitudinal RV systolic function may be quantified by the tricuspid annular plane systolic excursion (TAPSE) or the lateral tricuspid annulus tissue Doppler systolic wave velocity (S′). The TAPSE is well validated against more complex measurements of RV systolic function. TAPSE values are impaired post cardiac surgery after the pericardium is opened, although radial contractility usually compensates for the decrease in longitudinal movement. Measurement of RV fractional area change (FAC) offers a more global measure of RV systolic function but is less reproducible. Newer technologies such as 3D echo and strain require further evaluation within the critical care setting.[13-15]

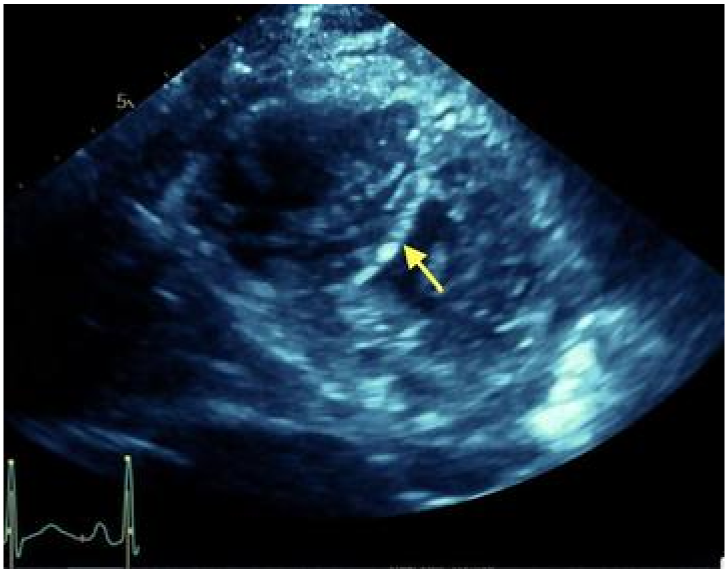
Interventricular septal curvature and movement should be examined for signs of RV volume or pressure overload. RV volume overload causes flattening (leftward shift) of the interventricular septum, with a characteristic D-shaped LV cavity in cross-section, during diastole. LV pressure overload causes septal flattening predominantly during systole (Fig. 25.2).



LVOT Vmax 0.94 m/s
LVOT Vmean 0.72 m/s
LVOT maxPG 3.57 mmHg
LVOT meanPG 2.25 mmHg
LVOT VTI 17.9 cm
LVOT Env.Ti 249 ms
HR 104 BPM

The Doppler echocardiography spectral tracing of flow through the L V outflow tract shows a sector view and a spectral graph. At the top centre, a triangular sector view displays colour flow mapping within the heart. Below this, a vertically oriented spectral graph exhibits a pulsatile velocity profile with time on the horizontal axis and velocity on the vertical axis. The graph contains repetitive waveforms with dense vertical streaks, and a fine turquoise outline traces the upper contour of each waveform cycle. Multiple peaks are marked numerically. A list of values is displayed in the upper left corner. L V O T V max is 0.94 metres per second. L V O T V mean is 0.72 metres per second. L V O T maximum pressure gradient is 3.57 millimetres of mercury. L V O T mean pressure gradient is 2.25 millimetres of mercury. L V O T velocity time integral is 17.9 centimetres. L V O T ejection time is 249 milliseconds. Heart rate is 104 beats per minute. The vertical axis scale ranges from 0.2 to negative 1.2 metres per second. The horizontal axis has labelled intervals from negative 4 to 6.

FIG. 25.1 Flow through the LV outflow tract (LVOT).



The echocardiographic view shows the heart within a triangular scanning sector. Multiple concentric and layered soft tissue structures are visible. A solid arrow is placed near the centre right portion, pointing toward a visibly flattened segment along the interventricular septum, which appears less curved than the adjacent myocardial walls. In the upper left quadrant of the sector, a depth reference with the number 5 is visible. A segment of an electrocardiogram waveform is shown in the lower left corner, displaying two upward deflections with small circular markers at the peak of each wave.

FIG. 25.2 Interventricular septal flattening.

Septal dyskinesia is also seen with intraventricular conduction disorders, septal infarction and after cardiac surgery.

Estimation of pulmonary artery pressure is an integral part of right heart evaluation. RV systolic pressure (RVSP) can be estimated from peak tricuspid regurgitant jet velocity (max TR velocity), where $\text{RVSP}=4(\text{max TR velocity})^2+\text{right atrial pressure}$. RA pressure should be directly transduced from an upper-body central venous line where present. In the absence of pulmonary stenosis, systolic pulmonary artery pressure approximates RVSP. Pulmonary hypertension is fairly likely to be present if the tricuspid regurgitant jet velocity is greater than 2.8 m/s, and highly likely if >3.4 m/s.[16] Advanced techniques may be used to estimate mean and diastolic pulmonary artery pressures.

Valvular Assessment

Detection of significant valve pathology is important in critically ill patients. In some, it may be a major cause of instability; in others, preexisting valvular pathology may complicate the management of another problem (Table 25.4) .[17]

Table 25.4

EF , ejection fraction; *FAC* , fractional area change; *IVC* , inferior vena cava; *LV* , left ventricle; *LVEF* , left ventricular ejection fraction; *RV* , right ventricle; *RVSP* , right ventricular systolic pressure; *TAPSE* , tricuspid annular plane systolic excursion.

Adapted from Vieillard-Baron A, Millington SJ, Sanfilippo F, et al. A decade of progress in critical care echocardiography: a narrative review. *Intensive Care Med* . 2019;45(6):770-788. doi: 10.1007/s00134-019-05604-2 .

First, clear visualisation of valves, ideally zoomed and taken from multiple windows, is important in excluding major structural problems (e.g. thickened/calcified leaflets with poor opening; a flail or prolapsing leaflet; endocarditis). Colour Doppler imaging is used to detect abnormal flow patterns, consistent with stenosis or valvular regurgitation. Relying on the area of a colour Doppler jet alone to determine regurgitation severity is not recommended unless it appears only mild, due to inaccuracies from gain, scale and eccentric flows. [18], [19] For example acute severe regurgitation leads to rapid equalisation of pressures between the two chambers, and as such, the regurgitant jet may be short-lived and small in area, and its severity underestimated. Extra assessment (such as assessing for abnormal upstream or downstream flow), or additional techniques (e.g. vena contracta diameter), are recommended to confirm the impression based on colour Doppler, for the more advanced practitioner. Eccentric, wall-hugging regurgitant jets are more severe than they might otherwise appear, due to the constraint of the regurgitant jet (Coanda effect).

Diagnosis of valvular stenosis starts with visualisation of an abnormally thickened valve with restricted opening, often with calcification. Colour Doppler may help identify flow acceleration. Measuring peak and mean transvalvular pressure gradients (by tracing the VTI signal), or velocities, also obtained using continuous wave (CW) Doppler, may help with the estimation of the severity of the stenosis. Importantly, velocities and pressure gradients are flow and load dependent, and should not be used in isolation. For instance, the pressure gradient across a stenotic mitral or aortic valve will increase in a hyperdynamic patient. The converse is also true, as seen in 'low-flow, low-gradient severe aortic stenosis' with LV impairment. [20] However, pressure gradients from the outpatient population are helpful, for example a mean aortic valve gradient >20 mm Hg or a mean mitral gradient >5 mm Hg should raise suspicion of at least moderate stenosis. Effective valve orifice area may be calculated with the continuity equation.

Some important features and pitfalls when assessing for major valvular pathology in critical care patients are included in Table 25.5 .

Table 25.5

Important features and pitfalls when screening for major valve pathology in critical care (Low threshold for expert TTE assistance, ± TOE imaging of valve in unstable patient)

VALVE PATHOLOGY	BASIC FEATURES	COMMON CHALLENGES/ PITFALLS IN IDENTIFICATION	TIPS	EXAMPLE
Aortic stenosis	Thickened aortic valve with restricted opening	Poor visualisation of the valve itself Failure to identify the highest velocity jet across the valve Low flow, low-gradient severe aortic stenosis (low gradient in the setting of poor LV function)	Look for significant AS if there is increased LV wall thickness Spend time looking for maximum gradient across aortic valve, from multiple angles/ windows Use ratio of peak velocities or VTI (LVOT to aortic), the 'dimensionless index'	 AV Vmax 4.89 m/s AV Vmean 3.71 m/s AV maxPG 95.62 mmHg AV meanPG 62.03 mmHg AV VTI 104.6 cm AV Env.Ti 282 ms HR 213 BPM 145/44 10 15
Mitral stenosis	Thickened mitral valve leaflets with abnormal opening (often 'hockey-stick' appearance in presence of rheumatic mitral valve disease)	Failure to visualise mitral valve opening, or put colour Doppler across mitral valve in A4C/A2C view Failure to appreciate that a mean gradient across the mitral valve of 5 mm Hg is significantly elevated	Patient will have dilated left atrium Use colour Doppler across mitral valve in apical view Continuous wave Doppler will show increased transmitral inflow velocities (>1 m/s) and mean pressure gradient usually > 5 mm Hg (see text)	 
If signs of valvular stenosis or abnormal regurgitation are identified, comprehensive evaluation is indicated. Comprehensive echocardiography is also indicated for evaluation of prosthetic valve function, or if endocarditis is suspected.

Prosthetic Valves

Prosthetic valves are inherently stenotic compared to native valves. Thus it may be difficult to distinguish mild obstruction due to valve design from that due to pathological changes or prosthesis-patient mismatch. As a rule, unexplained haemodynamic instability in the presence of a prosthetic valve necessitates the exclusion of prosthetic valve malfunction. Expert echocardiography is required, often including TOE to visualise the prosthesis more clearly. This may need to be complemented by other imaging modalities, such as MRI, CT and fluoroscopy.

Fluid Responsiveness and Fluid Overload

The question of ‘fluid responsiveness’ is an area of interest but also of controversy within echocardiography and critical care, where terms such as ‘fluid responsive’ lack universally agreed definitions. [21] Moreover, there is no agreement as to the optimal response to this finding. Fluid responsiveness has been defined as a significant increase in stroke volume (often taken to be >10%), in response to fluid loading, with minimal change in CVP. [22] Echocardiography can be used to predict this, as can clinical assessment (e.g. the haemodynamic response to passive leg raising (PLR)), or the two may be combined. The latter strategy may help ensure that false-positives (e.g. acute cor pulmonale) leading to pulse-pressure variation are identified, and fluid is not administered where it might be harmful.

Preload, which is the cardiac load present at end-diastole (e.g. LV end-diastolic cavity size), has been shown to be a poor predictor of fluid responsiveness. [23] One exception is in the setting of overt hypovolemia, which may be seen as a markedly decreased LV end-diastolic area (LVEDA) (usually less than $10\ \text{cm}^2$, measured in the parasternal mid-short-axis view).

Dynamic indices apply the Frank-Starling law of the heart and ventricular interdependence to examine the effect of a change in preload on stroke volume or systemic venous return. If the LV is operating on the steep ascending part of the ventricular function curve, then changes in preload will be associated with variation in stroke volume, and predict fluid responsiveness. However, assessing beat-to-beat stroke volume variation with respiration in mechanically ventilated patients requires several important conditions (such as spontaneous respiratory effort, no arrhythmias, no significant LV or RV dysfunction and no intra-abdominal hypertension). [24] Conversely, assessing for changes in stroke volume over multiple beats with the PLR method is possible in the majority of critically ill patients, whether intubated or not. [25]

Interpretation of IVC size and distensibility depends, once again, on the presence or absence of mechanical ventilation. [22] With TOE, superior vena cava (SVC) collapsibility performs better than IVC variation in predicting fluid responsiveness in mechanically ventilated patients. [26]

An echocardiographic assessment of fluid overload involves integrating assessment of the left heart, lungs, right heart and venous system. Venous congestion assessment by ultrasound involves the measurement of IVC size and respiratory variation. More recently, there has been interest in combining this with hepatic, portal, renal and femoral vein Doppler. [27]

Diastolic Function and Left Atrial Pressure

Diastolic dysfunction in critically ill patients and perioperative period has been associated with both ventilatory weaning failure and mortality. [28] Impaired diastolic function manifests as an increased a higher tendency to cardiogenic pulmonary oedema due to raised left atrial pressures, and a reduced capacity of the LV to increase stroke volume in response to physiological stress. Diastolic dysfunction should be suspected if there is LV hypertrophy or left atrial (LA) enlargement.

Echocardiography guidelines for the diagnosis of diastolic dysfunction updated in 2016, [29] are ‘not necessarily applicable in the perioperative setting’, and their extrapolation to critical care requires caution. [30] For instance, an elevated TR jet velocity may be elevated due to pulmonary pathology (e.g. pneumonia) and/or positive pressure ventilation rather than diastolic dysfunction. In addition, mitral inflow velocities (E) alter markedly with intravascular volume status.

Of the recommended features, e’ (maximal myocardial relaxation velocity, a preload independent measure) and E/e’ (the ratio of mitral inflow velocity to myocardial relaxation velocity) may be the most useful. E/e’ correlates with LA pressures; a normal value is <8, whereas a ratio above 13–15 in mechanically ventilated patients has been associated with pulmonary artery occlusion pressures >18 mm Hg.[31] As such, there is a ‘grey zone’ between likely normal and likely elevated LA pressures using E/e’. Importantly, e’ is unreliable in the setting of adjacent LV segmental dysfunction and mitral valvular and annular pathology. LA dilatation is another sign of impaired diastolic function, but not specific to this. The position of the interatrial septum, with fixed bowing from left to right, is another sign that LA pressures exceed RA pressures.

Combining echocardiography with lung ultrasound is particularly important in assessing pulmonary oedema, and its likely cause. The presence of B lines on lung ultrasound, consistent with interstitial lung pathology, is more sensitive than the chest X-ray in the detection of pulmonary oedema[32] and may allow differentiation of acute respiratory distress syndrome (ARDS) ‘inflammation’ from ‘hydrostatic’ pulmonary oedema.[33]

Pericardial Effusion and Tamponade

Echocardiography is the preferred imaging modality to detect a pericardial effusion and for assessing its physiological effects. A trivial effusion is only seen in systole, a small effusion measures less than 1.0 cm, a moderate effusion 1.0–2.0 cm and a large effusion greater than 2.0 cm, measured at end-diastole.[34]

A pericardial effusion is distinguished from pleural effusion by its anatomical relationship to the descending aorta; pericardial fluid only tracks anterior to the descending aorta, whereas a pleural effusion does not. TOE may be necessary to demonstrate localised pericardial fluid collections, especially post cardiac surgery.[35] Fat within the pericardium (lipomatosis) can be extensive and can be clinically significant if compounded by hypovolaemia; on M-mode fluid appears as a black anechoic stripe, fat as sequential silver lines.

Both the rate of accumulation and volume of a pericardial effusion determine the degree of physiological compromise. Importantly, small, rapidly accumulating effusions may cause tamponade. Cardiac tamponade comprises a continuum, from an effusion causing minimal effect to circulatory collapse.

Pericardial tamponade occurs when intrapericardial pressure exceeds intracardiac pressures causing cardiac chamber compression, increased ventricular interdependence, venous obstruction and haemodynamic compromise. Intrapericardial pressures may reach 15–20 mm Hg. [35] In the structurally normal heart, the lowest intracardiac pressures occur in the right atrium during ventricular systole and the RV during early diastole. Thus with increasing intrapericardial pressure, chamber compression manifests at first as systolic right atrial free wall collapse, and subsequently as RV-free wall collapse in early diastole, extending later in diastole as intrapericardial pressures increase further. These features may be influenced by intravascular volume status and right-sided heart pressures.

Once LV filling starts to be impaired, the LV diastolic wall thickness may increase (‘pseudohypertrophy’) [36] and its stroke volume falls. RV chamber collapse is best appreciated in the subcostal four-chamber view, where the right heart lies close to the probe. In the presence of pulmonary hypertension and RV hypertrophy, right-sided free wall collapse occurs at higher intrapericardial pressure and left-sided compression may occur first. Localised, left-sided tamponade may lead to pulmonary oedema in addition to shock.

Restrained ventricular filling in the presence of a pericardial effusion causes increased ventricular interdependence. In the absence of positive pressure ventilation, this manifests as exaggerated respiratory variation in transmitral and tricuspid blood flow, and cyclical movement of the interventricular septum with respiration (‘septal bounce’) as one ventricle fills at the expense of the other. Notably, marked respiratory variation in blood flow can also occur with acute respiratory disease due to large swings in intrathoracic pressure, RV disease or hypovolaemia. However, in patients on positive pressure ventilation, respiratory variation in blood flow is in fact decreased (rather than increased) by the presence of tamponade. [37] Fixed IVC dilatation is present whether the patient is spontaneously breathing or mechanically ventilated.

Given the challenges in the assessment of pericardial effusion by echocardiography, particularly in the intubated patient, echocardiographic signs need to be integrated with the clinical picture. In the shocked patient, a definitive diagnosis of tamponade can sometimes only be made after seeing haemodynamic improvement after drainage of a pericardial effusion.

When performing pericardiocentesis, echocardiography can guide the best approach (apical versus subxiphoid), confirm pericardial entry of the needle (e.g. injecting agitated saline), and confirm guidewire and catheter placement.

Transoesophageal Echocardiography

Transoesophageal echocardiography (TOE) provides better image quality of many cardiac structures compared to transthoracic imaging because of reduced imaging distance, higher frequency transducers and lack of intervening chest wall and lung. Posterior cardiac structures such as the left atrium, mitral valve, pulmonary veins and aorta are particularly well imaged, whereas right-sided structures (e.g. tricuspid valve) may be better imaged with TTE. In some settings (e.g. major trauma, surgical emphysema, post cardiac surgery and suspected prosthetic valve endocarditis) TOE may help make important diagnoses that cannot be made on TTE due to imaging challenges.

TOE is a semi-invasive procedure that is relatively contraindicated in the setting of oesophageal disease (e.g. stricture, tumour, perforation and diverticulum) and active upper GI bleeding. There are also pathologies (e.g. non-bleeding varices, severe coagulopathy), [38] where the risk-benefit of proceeding needs consideration. [39] Oesophageal perforation remains uncommon, estimated at <0.1% in one non-ICU series [40] but major complications are often not reported. Some limitations of TOE include the inability to obtain true anatomical measurements due to oblique imaging planes, difficulty obtaining Doppler beam alignment resulting in underestimation of velocities, and inability to visualise the distal ascending aorta and proximal aortic arch. There are increasing applications for point-of-care ultrasound using TOE. [41]

Clinical Scenarios

Many specialist societies have indications for critical care TTE and TOE, as well as recommendations for levels of training. [42-44] Simply put, in an acutely unwell patient with shock, cardiac or respiratory failure, an echocardiogram is typically indicated. Recent evidence-based guidelines for the utility of point-of-care ultrasound (POCUS) in common clinical scenarios are available. [45]

The type of study (basic versus comprehensive and transthoracic versus transoesophageal) will depend on the clinical situation, availability of equipment and the echocardiography expertise of the attending clinician. Most often, a focused study, with a basic assessment of valvular function, will suffice to answer a clinical question. [46] Repeated studies in unstable patients may allow the response to interventions to be assessed. In other words, a diagnostic device becomes a monitor.

Haemodynamic Instability

Combining focused assessment of LV and RV systolic function, RV and LV preload, the pericardium, valves and stroke volume (for more experienced users) may rapidly allow the mechanism of shock to be categorised. [44] Combining cardiac assessment with other focused examinations (e.g. lung and abdomen) will yield further information.

Dynamic LVOT obstruction is a common cause of shock in the critically ill. This may be favoured by predisposing factors including a narrowed LVOT (e.g. septal hypertrophy) and mitral valve anatomy but is often precipitated by high flow states, hypovolemia and inotrope use, leading to the mitral valve being drawn into the outflow tract in systole, obstructing outflow. Echocardiography demonstrates a late-peaking (‘dagger-shaped’ on CW Doppler) turbulent jet in the LVOT, often associated with a posteriorly directed jet of mitral regurgitation that may be severe. Where patients remain hypotensive on high doses of inotropes with a hyperdynamic or hypovolaemic echocardiogram, the correct management, on occasions unnerving, is typically less inotropic support and monitored fluid loading (Fig. 25.3).

The M-mode echocardiographic tracing shows the left ventricle. At the top centre, a narrow sector scan displays a vertical scan line intersecting the cardiac structure. Beneath this, the M-mode tracing exhibits continuous horizontal bands forming repeating undulations that represent motion of the ventricular walls over time. Two opposing curved lines outline the motion of the anterior and posterior walls. A set of measurement callipers is placed between the walls to mark the internal chamber width. On the lower left, a vertical menu lists categories such as V d, R V D, R V W, I V S, L V P W, and L V D, with L V D selected. Along the bottom edge, numeric values are displayed as L V D during diastole equals 2.18 centimetres and L V D during systole equals 0.52 centimetres. Additional interface elements include numeric markers on the right margin and a percentage value for E F displayed as 98.

FIG. 25.3 Kissing papillary muscle hypovolaemaia.

Acute Coronary Syndrome

A change in clinical status following an acute coronary syndrome should prompt echocardiography to detect complications as follows:

- Complete or partial papillary muscle rupture usually causes severe, acute *mitral regurgitation.*
- *LV failure* causing a low cardiac output state.
- *Ventricular septal rupture* causes cardiogenic shock; on echocardiography, one or more septal defects can be detected with colour Doppler. LV function may appear deceptively good due to offloading to the RV. *LV free wall rupture* causes very rapid accumulation of pericardial blood with severe tamponade.

RV infarction is differentiated from acute cor pulmonale by the absence of pulmonary hypertension and coexistence of LV inferior wall hypokinesia.

Septic Shock

Septic myocardial depression is the cardiovascular manifestation of the multi-system disorder of septic shock. [47] Echocardiography-guided management may improve the outcomes of patients with sepsis. [48] While a common perception persists that sepsis produces a vasodilated, hyperdynamic state, some degree of impaired LV function is an almost universal finding in septic shock, as suggested by detecting biomarkers of myocardial injury. [49] In some patients, LV systolic failure may be severe and the primary haemodynamic abnormality producing shock. Echocardiography is well suited to provide rapid and repeated evaluation of the haemodynamic state. LV dysfunction may be ‘unmasked’ after pressor therapy is commenced, increasing LV afterload.

Respiratory Failure

Echocardiography is useful for evaluating the cause and haemodynamic consequences of respiratory failure. Firstly, in patients with pulmonary infiltrates on chest radiograph, examination of the left heart is focused on findings that may predispose to cardiogenic pulmonary oedema such as LV systolic dysfunction, diastolic dysfunction or left-sided valvular heart disease.

Secondly, examination of the right heart is focused on identifying signs of acute cor pulmonale and quantifying the severity of pulmonary hypertension. Acute cor pulmonale is the result of a sudden increase in RV afterload, caused by ARDS or pulmonary embolism. Patients with more severe ARDS may develop acute cor pulmonale due to a combination of pulmonary vascular dysfunction, hypoxia, hypercarbia and high intrathoracic pressures. [50] On echocardiography, acute cor pulmonale is characterised by RV dilatation and interventricular septal dyskinesia with septal flattening in late systole (D-shaped LV in short axis).

Thirdly, in patients with hypoxaemia disproportionate to the severity of underlying illness, a bubble study during echocardiography can be used to identify a right-to-left shunt through a patent foramen ovale or atrial septal defect or intrapulmonary shunt (e.g. with hepatopulmonary syndrome).

Pulmonary Embolism

Echocardiography can be an essential tool in the assessment of an unstable patient with suspected or known pulmonary embolus, including where computed tomography may be unsafe. The echocardiographic signs of high-risk pulmonary embolism, defined by the presence of shock or persistent hypotension, are those of acute right heart failure, with impaired RV systolic function and RV pressure overload. The RV may be dilated. There may be an increased severity of tricuspid regurgitation, permitting the demonstration of pulmonary hypertension and interventricular septal bulge towards the LV. Occlusive thrombus may be seen (for example in the main pulmonary artery on TOE), and rarely, thrombus may be directly visible in transit through the right heart. In addition, the combination of RV-free wall hypokinesis and relative sparing of apical systolic function (McConnell sign) has a high (but not 100%) specificity [51] but low sensitivity for pulmonary embolism.

Absence of echocardiographic signs of acute cor pulmonale effectively excludes pulmonary embolism as the cause for haemodynamic compromise. Conversely, the presence of acute cor pulmonale in the appropriate clinical setting may be used to justify thrombolysis therapy.

Failure to Wean from Mechanical Ventilation

During the transition from mechanical ventilation to spontaneous breathing, the change in ventricular loading conditions may unmask occult systolic or diastolic dysfunction. Echocardiography should be combined with lung ultrasound to detect signs of acute pulmonary oedema (B lines) and assess diaphragmatic function.

Post Cardiac Surgery

The early postoperative period after cardiac surgery presents unique challenges to image optimisation due to mechanical ventilation, surgical dressings and drains and to image interpretation because of diagnostic findings unusual in other clinical settings:

Pericardial haematoma can cause focal cardiac chamber compression; thus every cardiac chamber must be clearly visualised. Rarely, massive haemothorax can cause tamponade.

Dynamic LVOT obstruction should be suspected in the patient with mitral valve repair, hypertrophic LV or aortic valve replacement for aortic stenosis, who develops shock that fails to respond to catecholamines.

RV dysfunction may occur in isolation, for example due to inadequate intraoperative cardioplegia or passage of air down the right coronary artery.

Patient prosthesis mismatch results in a high transvalvular pressure gradient and difficulty weaning from mechanical ventilation. Other causes of prosthetic valve dysfunction (e.g. leaflet entrapment or paravalvular leak) warrant expert evaluation.

Cardiac Arrest

Echocardiography may be useful during cardiac arrest with non-shockable rhythms to assess myocardial contractility and help identify potentially reversible causes such as pericardial tamponade, pulmonary embolism, hypovolaemia or tension pneumothorax. Detection of cardiac activity in patients in a non-shockable rhythm (such as ‘pseudo-PEA’, perhaps better viewed as profound hypotension), has been associated with a higher likelihood of return of spontaneous circulation.[52] Subxiphoid placement of the TTE probe just before chest compressions are paused for a planned rhythm assessment allows image acquisition within 10 seconds during the pause.[53] TOE may provide better imaging quality than transthoracic echocardiography without interruption of chest compressions.

Inotropes and vasopressors (vasoactive drugs)

Adam M. Deane, Ashish K. Khanna and John Myburgh

Introduction

The pharmacological support of the failing circulation is a fundamental component of acute medicine. The principal aim of these drugs is to restore inadequate systemic and regional perfusion to physiological levels.

Definitions

Inotropic agents are drugs that act on the heart by increasing the velocity and force of myocardial fibre shortening. The consequent increase in contractility results in increased cardiac output and systemic blood pressure.

Vasopressors are drugs that have a predominantly constrictive action on the peripheral vasculature, both arterial and venous, to increase mean arterial pressure.

The distinction between an inotrope and a vasopressor is an arbitrary one. Given the overlap of pharmacodynamic effects of these drugs, **the term 'vasoactive therapy' is a more appropriate description** .

Historically, clinical practice has been informed by physiological and pharmacological principles, anecdotal clinical experience, institutional preferences and drug availability. This led to wide variation in clinical practice relating to the use of vasoactive drugs. More recently, high-quality randomised clinical trials have been published that provide a greater evidence base to inform clinical practice.

The most frequently used vasoactive drugs are the naturally occurring catecholamines, noradrenaline (norepinephrine) and adrenaline (epinephrine), which have both positive inotropic and protean effects on the venous and arteriolar vasculature.

Characteristics of the ideal vasoactive drug are shown in Box 26.1 .

Box 26.1

The ideal inotrope

- Increases contractility
    - Increases mean arterial pressure
    - Increases cardiac output
    - Improves regional perfusion
- No increase in myocardial oxygen consumption
    - Avoidance of tachycardia
    - Non-arrhythmogenic
    - Maintenance of diastolic blood pressure
- Does not develop tolerance
- Titratable
    - Rapid onset
    - Rapid termination of action
- Compatible with other drugs
- Non-toxic
- Cost effective

Catecholamines

Sympathomimetic amines include the naturally occurring catecholamines noradrenaline and adrenaline and synthetic vasoactive agents such as dobutamine.

Receptor Biology

Catecholamines bind to populations of adrenergic receptors that have been divided into α and β groups. Further subgroups of α- and β-receptors (e.g. α1, α2, β1, β2 and β3) have been identified. [1]

Adrenergic receptors belong to the superfamily of G protein-coupled receptors. It has been estimated that there are 600 to 1000 different types of G protein-coupled receptors. These receptors are expressed in virtually all tissues and result in diverse physiological responses. [2]

This complex agonist–receptor–effector relationship may vary depending on pathological conditions. Situations can arise such that adrenergic receptors no longer respond to physiological or pharmacological sympathetic stimulation to the same extent (desensitisation); and/or reduced density, sequestration and enzymatic uncoupling of adrenergic receptors result in impaired responses (down-regulation). [3]

Biosynthesis

The biosynthesis and chemical structures of the naturally occurring catecholamines are shown in Fig. 26.1A .

The two-part diagram is labelled A and B. Part A presents a schematic representation of the biosynthesis of catecholamines in sympathetic terminals. The pathway begins with phenylalanine converting into tyrosine, then to Dopa, and further into dopamine, which is released into the synaptic cleft. The conversion from tyrosine to Dopa is marked as the rate limiting step and is catalysed by tyrosine hydroxylase. Dopamine acts on a labelled structure and is further metabolized or converted to norepinephrine, which interacts with a postsynaptic cell containing receptors labelled alpha 1, beta 1, 2 and 3. A feedback loop involves alpha 2 receptors. Norepinephrine can be further converted into epinephrine through the action of P N M T. Additional elements include the adrenal gland and two enzymes, C O M T and P N M T. Part B presents chemical structures of six catecholamines. From top to bottom and left to right, they are dopamine, norepinephrine, epinephrine, isoprenaline, dobutamine, and dopexamine. Each molecule is shown with its respective benzene ring and labelled functional groups such as C H 2 C H 2 N H 2, H C O H C H 2 N H 2, and extended side chains ending with hydrochloride or dichloride notations. The top three are endogenous compounds, and the bottom three are synthetic catecholamines.

FIG. 26.1 (A) Biosynthesis of catecholamines in sympathetic terminals. *, Rate-limiting step by tyrosine hydroxylase; *COMT* , catechol- *o* -methyl-transferase; *PNMT* , phenethanolamine- *N* -methyltransferase. (B) Chemical structure of endogenous and synthetic catecholamines.

Catecholamines consist of an aromatic ring attached to a terminal amine by a carbon chain. The configuration of each drug is important for determining affinity to respective receptors.

Dopamine is hydroxylated to form noradrenaline, which is the predominant peripheral sympathetic neurotransmitter in humans acting at all adrenergic receptors. The release of noradrenaline from sympathetic terminals is controlled by re-uptake mechanisms mediated via α2-receptors and augmented by adrenaline released from the adrenal gland at times of stress. Noradrenaline is converted to adrenaline, which is subsequently metabolised in the liver and lungs.

All catecholamines have short biological half-lives (1–2 minutes) and a steady state plasma concentration is achieved within 5–10 minutes after the start of a constant infusion. This allows rapid titration of drug to a clinical response, such as mean arterial pressure.

The synthetic catecholamines are primarily derivatives of dopamine (see Fig. 26.1B). These agents are characterised by the increased length of the carbon chain that confers affinity for β-receptors. These agents have a relatively low affinity for α-receptors due to the configuration of the terminal amine, which differs from the endogenous catecholamines.

Adrenaline and noradrenaline have hydroxyl groups on the β-carbon atom of the side chain, and this is associated with 100-fold greater potency than dobutamine.

Systemic Effects

The systemic effects of these drugs vary between patients and within individual patients over time. The adequacy of response is unpredictable and depends on the adequacy of host response which is primarily determined through endotype and phenotypic expression, the aetiology of circulatory failure and co-existing chronic diseases. In some patients, marked responses to small doses may occur characterised by a sharp increase in mean arterial pressure, whereas in others progressively increasing doses of vasoactive drugs are required to attain a targeted mean arterial pressure.

The classification of sympathomimetic agents into α- and β-agonists, based on the above structure–function relationships, is a widely used, albeit unreliable, predictor of systemic effects (see Table 26.1).

Table 26.1

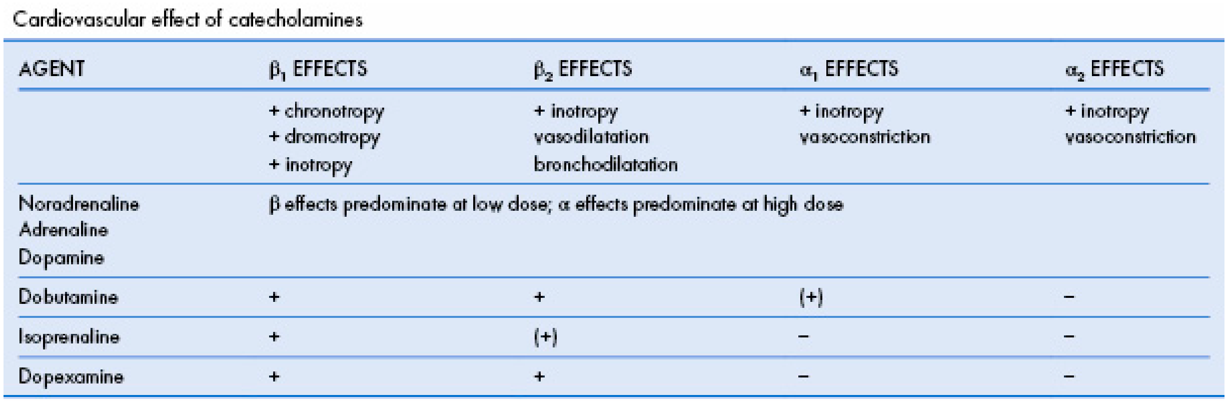
cAMP , cyclic adenosine monophosphate.

Adrenaline and noradrenaline are predominantly β-agonists at lower doses, with increasing α-effects becoming evident as the dose is increased. The synthetic catecholamines are predominantly β-agonists.

Cardiovascular

The cardiovascular effects of the catecholamines under physiological conditions are shown in Table 26.2 .

Table 26.2

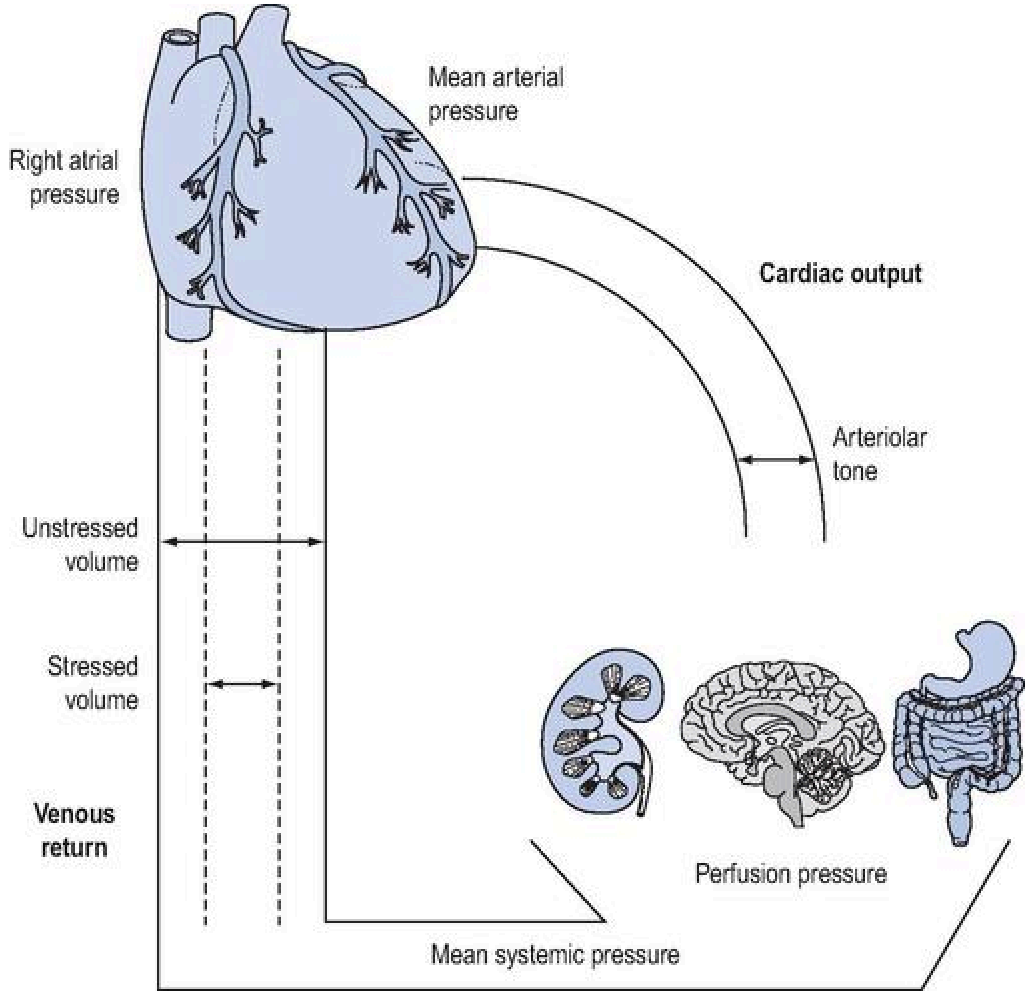


Cardiovascular effect of catecholamines

AGENT	β_1 EFFECTS	β_2 EFFECTS	α_1 EFFECTS	α_2 EFFECTS
	+ chronotropy + dromotropy + inotropy	+ inotropy vasodilatation bronchodilatation	+ inotropy vasoconstriction	+ inotropy vasoconstriction
Noradrenaline Adrenaline Dopamine	β effects predominate at low dose; α effects predominate at high dose			
Dobutamine	+	+	(+)	−
Isoprenaline	+	(+)	−	−
Dopexamine	+	+	−	−

+, Stimulation; (+), mild effect; −, no effect.

Noradrenaline and adrenaline increase stroke volume, cardiac output and mean arterial pressure, with variable chronotropic responses. Dopamine is associated with an increased incidence of dysrhythmias compared to adrenaline and noradrenaline. [4] The effects on the vasculature are similar, primarily increasing venous return without changes in the resistance to venous return or in calculated systemic vascular resistance (Fig. 26.2).



Mean arterial pressure
Right atrial pressure
Cardiac output
Arteriolar tone
Unstressed volume
Stressed volume
Venous return
Perfusion pressure
Mean systemic pressure

The diagram presents the dynamic relationship between cardiac output, venous return, and pressure variables in the cardiovascular system. A stylised heart is shown on the upper left, labelled with mean arterial pressure and right atrial pressure. An arrow originating from the heart curves downward and rightward, labelled cardiac output, and connects to three anatomical illustrations of a kidney, brain, and intestine, collectively marked as perfusion pressure. Arteriolar tone is labelled along the curved pathway. Another curved path labelled mean systemic pressure leads back toward the heart, continuing vertically as venous return. This vertical path is separated into two labelled parts, with the lower segment marked stressed volume and the upper segment marked unstressed volume. The entire arrangement reflects the interconnected flow of blood and associated pressures throughout the circulatory system.

FIG. 26.2 Schematic relationship of the determinants of cardiac output and venous return.

The profile of dobutamine differs from the naturally occurring catecholamines with variable responses in mean arterial pressure and heart rate. Frequently, a reduction in mean arterial pressure occurs due to reduced venous return.

In the failing myocardium, particularly in patients with cardiac failure following cardiopulmonary bypass or septic shock, endogenous stores of noradrenaline are markedly reduced. [5] There may be significant desensitisation and down-regulation of cardiac β-receptors. In these situations, α1- and α2-receptors have an important role in maintaining inotropy and peripheral vaso-responsiveness. This may be expressed clinically as tolerance or tachyphylaxis to catecholamines, particularly with β-agonists such as dobutamine. This phenomenon may explain the requirement for high doses of catecholamines in refractory shock states.

Catecholamines act predominantly on the venous circulation, primarily restoring and maintaining ‘stressed volumes’ of the capacitance vessels under pathological conditions. This is important in ‘vasodilatory’ states such as septic shock. [6]

In clinically used doses, intravenously administered catecholamines have no direct vasoconstrictive effect on conducting arterial vessels, including arterial conduits used in cardiac or vascular surgery.

The development of peripheral gangrene in refractory septic shock has been attributed to catecholamine-induced vasoconstriction but the association with tissue gangrene is predominately due to sepsis-mediated coagulaopathy and intravascular thrombosis. Any impact of drug-induced vasoconstriction is modest in comparison to the primary disease.

Cerebral

Under physiological conditions, catecholamines do not cross the blood–brain barrier. Cerebral blood flow is maintained at a constant rate over a range of perfusion pressure by cerebral autoregulation. Under conditions where the integrity of the blood–brain barrier is altered, such as following traumatic brain injury and aneurysmal subarachnoid haemorrhage, exogenous catecholamines may directly enter the cerebral circulation.

There is uncertainty about the direct cerebrovascular effects of catecholamines in patients with traumatic brain injury, although there is some evidence suggesting that dopamine may exert a direct effect causing increased cerebral blood flow and intracranial pressure. [7]

Renal

The kidney is an efficient autoregulator, maintaining constant glomerular filtration and renal blood flow by neurohormonal mechanisms such as the renin–angiotensin–aldosterone system. [8] The pathophysiological effect of shock on the kidney is detailed in Chapter 53 (Overview of Acute Kidney Injury). All catecholamines increase renal blood flow to a similar extent by increasing cardiac output and mean arterial pressure with a resultant natriuresis, but there is no proven benefit to patient outcomes by increasing vasoactive drugs to target a mean arterial pressure much greater than a range of 60 to 65 mm Hg. [9]

A natriuresis may also result from the inhibition of cAMP in the renal tubules. This effect has previously been attributed to a specific dopaminergic effect but there is now strong evidence that dopamine does not specifically protect against renal dysfunction. [10,11]

Metabolic

Catecholamine-mediated β-stimulation may result in hyperglycaemia, hypokalaemia and hypophosphataemia that may need monitoring and correcting.

Adrenaline is associated with the development of hyperlactataemia due to the activation of pyruvate dehydrogenase.[12] Although associated pH may fall to levels around 7.2, metabolic acidosis is not associated with impaired tissue perfusion or cellular dysoxia. In most patients who are haemodynamically stable, this is a self-limiting phenomenon and is not associated with adverse outcomes.[13], [14]

Splanchnic

The splanchnic circulation is dependent on mean arterial pressure and the duality of the mesenteric and portal systems. There is no evidence that vasoactive drugs cause mesenteric ischaemia.[15]

Rather, catecholamines are effective in increasing splanchnic perfusion by improving cardiac output and mean arterial pressure.

Phosphodiesterase inhibitors

Phosphodiesterase (PDE) inhibitors cause non-receptor-mediated competitive inhibition of PDE isoenzymes, resulting in increased concentrations of cAMP (see Fig. 26.3). Importantly, cAMP also affects diastolic heart function through the regulation of phospholamban, the regulatory subunit of the calcium pump of the sarcoplasmic reticulum. This enhances the rate of calcium re-sequestration and associated diastolic relaxation (lusitropy).[16]

The schematic diagram presents a layout of intracellular signalling pathways involved in calcium regulation within a cell. The central focus is a cell membrane enclosing a cytoplasmic compartment with multiple pathways converging on calcium transport. On the left, beta agonists and glucagon interact with beta 1, 2, 3 receptors and glucagon receptors, respectively. These act through G s and G i proteins to stimulate adenylyl cyclase. This converts A T P to cyclic A M P and activates downstream components such as phosphodiesterase type three, abbreviated as P D E I I I. Phosphodiesterase inhibitors block this action and maintain cyclic A M P levels. On the right side, alpha agonists bind to alpha 1 receptors, activating phospholipase C, which converts P I P 2 into I P 3 and I P

4. Both cyclic A M P and I P 3 modulate calcium release from the sarcoplasmic reticulum located centrally at the bottom of the diagram. Arrows represent movement of calcium into the cytoplasm from extracellular sources and internal stores. In the lower right, a circular label marks the sodium potassium pump, which is affected by digoxin. All components are shown within or acting across a single continuous cellular membrane border, illustrating interconnected mechanisms that regulate calcium availability in the cell.

FIG. 26.3 Schematic representation of the action of inotropic drugs on intracellular calcium in myocytes. *AMP* , Adenosine monophosphate; *ATP* , adenosine triphosphate; *cAMP* , cyclic AMP; *GR* , glucagon receptor; G_s , G protein complex; *IP3* , inositol phosphate 3; *PDE III* , phosphodiesterase III; *PIP2* , phosphoinositol diphosphate.

For cardiovascular tissue, inhibition of isoenzyme PDE III is responsible for the therapeutic effects. Cardiac effects are characterised by positive inotropy and lusitropy that may be beneficial in patients with reduced ventricular compliance or predominant diastolic failure. [13]

These agents also cause potent vasodilatation with reductions in preload, venous return and afterload as well as a reduction in pulmonary vascular resistance. The term ‘inodilation’ has been used to describe this dual haemodynamic effect.

Tolerance is not a feature of PDE inhibitors. These agents may have a role in sensitising the myocardium to β-agonists. Other actions include the inhibition of platelet aggregation and the reduction of post-ischaemic reperfusion injury.

The pharmacokinetics of PDE inhibitors are markedly different from catecholamines. Drug half-lives are longer, and excretion is predominantly renal. Hypotension may result from vasodilatation, and combined use with catecholamines (e.g. noradrenaline or adrenaline) may be necessary to maintain mean arterial pressure.

PDE inhibitors that have been used in clinical practice include the bipyridine derivatives, milrinone and the calcium sensitiser, levosimendan. The cardiovascular effects are similar. Despite the widespread use of PDE inhibitors in intensive care units, there is no evidence that these drugs improve patient-centred outcomes.[17-19]

Milrinone is the most used drug in clinical practice and exhibits more inotropic effects than vasodilation. Regardless of the cause of shock, there is no evidence that milrinone is superior to catecholamine administration.[20]

Levosimendan is a dose-dependent selective PDE inhibitor with a unique action on myocardial calcium metabolism. By increasing myofilament calcium sensitivity throughout the cardiac cycle by binding to cardiac troponin C, associated conformational changes induce positive inotropy and lusitropy. Vasodilatation is induced through adenosine-triphosphate-sensitive potassium channels. Calcium-sensitive actions predominate at lesser doses, whereas PDE-inhibition effects predominate at greater doses.[21] The half-life of levosimendan is shorter than that of older PDE inhibitors (approximately 1 hour). Randomised clinical trials have established that the use of levosimendan does not improve patient-centred outcomes.[17, 19]

Selective vasoconstrictors

Vascular responsiveness is mediated via adrenergic receptors: α-mechanisms predominantly cause vasoconstriction; β-mechanisms, specifically β_2-receptors, mediate vasodilatation (see Table 26.2). Noradrenaline, adrenaline and dopamine have variable effects on adrenoreceptors and should not be regarded solely as a vasoconstrictor. There are few selective ‘vasoconstrictors’ and their utility in critically ill patients remains limited, although they are widely used in patients undergoing general or regional (epidural) anaesthesia.

Phenylephrine and ***metaraminol*** are direct-acting α_2 agonists that are selective vasoconstrictors, both venous and arterial, with minimal β-activity. They have similar pharmacokinetics to catecholamines and may be given by infusion through a peripheral cannula. In patients with normal sympathetic tone, these drugs may cause reflex bradycardia, particularly following bolus administration.

Midodrine is an enterally administered drug that has an active metabolite with prominent α-activity. It had been proposed that this agent might allow more rapid weaning of intravenous catecholamines, thereby, facilitating earlier discharge out of ICU, but existing trials have not reported benefit with this approach. [22]

Non-catecholamine drugs

In addition to adrenergic regulation, neurohormonal influences have a regulatory role in maintaining vasomotor tone. These are mediated through the renin–aldosterone–angiotensin axis and local mediators such as vasopressin, corticosteroids, nitric oxide and endothelin.

The response of the neurohumoral system may become blunted in conditions such as severe sepsis, where qualitative and quantitative changes may occur.

Vasopressin

Specific vasopressinergic receptors have been identified in vascular smooth muscle (V_1), platelets (V_1), renal collecting duct (V_2) and anterior pituitary gland (V_3). Vasopressin is a naturally occurring peptide secreted by the posterior pituitary gland. When compared to health, serum concentrations of vasopressin are reduced in patients with septic shock and following cardiopulmonary bypass, suggesting an inflammatory-mediated mechanism. Endogenous vasopressin concentrations are maintained during cardiogenic shock. [23]

Exogenous vasopressin increases blood pressure and the addition of vasopressin results in a catecholamine-sparing effect. However, no reduction in mortality has been observed during randomised clinical trials when added to catecholamine infusion. [24-26] Existing evidence does not support the use of vasopressin prior to catecholamines. [25]

Selepressin/Terlipressin

Because of theoretical concerns with the actions of vasopressin on V_2 and V_3 receptors and the potential for water retention, prothrombotic effects and adrenocorticotropic hormone secretion, synthetic agonists that specifically target V_1 may be more effective than vasopressin.

Selepressin is a selective V_1 receptor agonist [27] but no clinically important benefits of adding selepressin to noradrenaline have been reported in patients with septic shock. [28]

Terlipressin is a selective V_1 receptor agonist with a longer half-life than selepressin. In patients with septic shock the use of terlipressin, when compared to noradrenaline as a first-line vasoactive drug, did not identify any meaningful benefit but an increase in adverse events, particularly related to digital ischaemia, was reported. [29]

Overall, there is no evidence that synthetic V_1 receptor agonists are superior agents to vasopressin and their use (either alone or with noradrenaline) is not recommended.

Angiotensin II

Under physiological circumstances, angiotensin-converting enzyme catalyses the conversion of angiotensin I to angiotensin II. Under pathological conditions such as septic shock or acute lung injury, dysregulation of angiotensin-converting enzyme may lead to an increased angiotensin I/angiotensin II ratio and resultant deactivation of calcium/calmodulin-dependent phosphorylation of myosin.

The use of synthetic angiotensin II peptide agonists has been developed as vasoactive drugs in patients with neuroendocrine dysregulation, such as septic shock, with a potential role as adjunctive therapy to the use of noradrenaline, corticosteroids and vasopressin on haemodynamic and renal effects. Recent randomised clinical trials have reported improvements in haemodynamic responses with a significant noradrenaline-sparing effect [30] and these drugs require further investigation to determine the effects on patient-centred outcomes.

Corticosteroids

The addition of ‘stress response’ doses (approximately 200 mg hydrocortisone per day by continuous intravenous infusion, or 50 mg 8 hourly) exerts a clinically important catecholamine-sparing effect, shorter time to reversal of shock and a reduction in the time to wean catecholamine infusions in patients with septic shock. [31], [32] The use of exogenous steroids in septic shock (Chapter 69) and support of the potential organ donor patient with shock (Chapter 113) are detailed elsewhere.

Methylene blue

Methylene blue is a dye that selectively inhibits nitric oxide synthase generation [6] with anecdotal reports that its use may be associated with beneficial haemodynamic catecholamine-sparing responses. Due to concerns about serious adverse events, it should not be used outside of clinical trials being conducted with suitable oversight. [33]

Clinical Uses

There is no definitive evidence that one vasoactive drug or combination is superior to another vasoactive drug, or combination, in improving patient-centred outcomes. There is no definitive evidence to inform the optimal timing when to commence vasoactive drugs (‘early’ vs. ‘late’). [34]

Drug Selection

Generally, individual and institutional experience and preferences determine the selection of vasoactive drug. In low- and middle-income countries, the cost and availability of the drug may determine choice.

Noradrenaline or adrenaline are considered the first-line drug in most causes of circulatory failure.

Because of the marked inter- and intra-individual variability to the response of vasoactive agents, the haemodynamic and metabolic response to an agent must be carefully monitored and evaluated.

Monitoring

Haemodynamic monitoring is detailed in Chapter 24 . Accurate monitoring of the circulation is essential in patients with circulatory failure to assess baseline parameters and the response of vasoactive drugs.

Clinical assessment of the circulation remains the cornerstone of monitoring. Clinical assessment includes frequent assessment and recording of pulse rate and rhythm, blood pressure, adequacy of peripheral perfusion, skin turgor, level of consciousness and urine output. Restoration of reduced tissue perfusion is a primary aim of vasoactive therapy. In addition to clinical signs, reversal of metabolic acidosis and reductions in serum lactate will identify response to treatment.

Most patients with circulatory failure managed in an ICU in high-income countries have continuous arterial monitoring, as clinical signs may be masked or influenced by sedation, ventilation or organ failure. When available, all patients receiving vasoactive drugs other than at trivial doses should have continuous arterial monitoring. However, hospitals in some regions may have limited access to arterial monitoring and clinicians may need to solely rely on clinical assessment. The requirement for continuous monitoring of volume status, such as the use of central venous pressure, is more contentious.

In selected patients with primary myocardial failure, an assessment of cardiac output may be useful to quantify baseline function and to assess the response of the heart to drug therapy. Measurement of cardiac output may be done non-invasively or invasively.

Dosages and Drug Administration

Vasoactive drugs are traditionally administered as a continuous infusion through a central venous catheter. More recent data suggests that adverse events when administered via a peripheral line are infrequent, so lesser doses of a single drug for a short duration appear safe.[35], [36]

Infusions of vasoactive drugs should occur using precise drug delivery systems such as infusion pumps or syringe drivers. Infusion lines should be free of injection portals and clearly marked with identifying labels. Concentrations of infusions should be standardised in accordance with individual unit protocols. Suggested infusion concentrations are shown in Table 26.3 . These infusions in mL/h approximate μg/min.

Table 26.3

Commonly used infusion concentrations for vasoactive drugs

AGENT	INFUSION CONCENTRATION	DOSE
Adrenaline	6 mg/100 mL 5% dextrose	Titrate mL/h (= µg/min)
Noradrenaline	6 mg/100 mL 5% dextrose	Titrate mL/h (= µg/min)
Dopamine	400 mg/100 mL 5% dextrose	Titrate mL/h (approx. µg/kg/min)
Dobutamine	500 mg/100 mL 5% dextrose	Titrate mL/h (approx. µg/kg/min)
Isoprenaline	6 mg/100 mL 5% dextrose	Titrate mL/h (= µg/min)
Milrinone	10 mg/100 mL 5% dextrose	Loading dose: 50 µg/kg over 20 min Infusion: 0.5 µg/kg/min
Levosimendan	25 mg/100 mL 5% dextrose	Loading dose: 24 µg/kg over 10 min Infusion: 0.1 µg/kg/min
Phenylephrine	10 mg/100 mL 5% dextrose	Titrate mL/h (= 100 µg/h)
Metaraminol	100 mg/100 mL 5% dextrose	Titrate mL/h (= mg/h)
Ephedrine	300 mg/100 mL 5% dextrose	Titrate mL/h (= 3 mg/h)
Vasopressin	20 U/20 mL 5% dextrose	2.4 mL/h (0.04 U/min)
Hydrocortisone	100 mg/100 mL 5% dextrose	Loading dose: 100 mg Infusion: 0.18 mg/kg/h

Vasoactive drugs are usually prescribed as a titration against a targeted mean arterial pressure.[37] Historically, the target mean arterial pressure frequently was 70 mm Hg. On an individual patient level, pre-morbid blood pressure, associated co-morbidities and acute illness will inform this target mean arterial pressure. However, targeting a specific threshold has not improved outcomes.[38-40] Recent trial data supports the concept that targeting a mean arterial pressure of 60 to 65 mm Hg in patients older than 65 years old is at least as safe, and may even be superior, to higher targets.[9]

Specific indications

Anaphylaxis

Adrenaline is the drug of choice for anaphylactic reactions and for life-threatening bronchospasm, as it blocks mediator release and specifically reverses end-organ effects (see Chapter 107).

Most international guidelines recommend 500 µg adrenaline is administered as an intramuscular injection.[41] While there is no evidence that the intramuscular route is superior to intravenous adrenaline (in doses up to 100 µg), repeated intravenous doses or infusions may be required.

Cardiopulmonary Resuscitation

Adrenaline has been used for circulatory collapse at least since 1907. The International Liaison Committee on Resuscitation guidelines recommend adrenaline as the first-line vasoactive drug in cardiopulmonary resuscitation.[42] The dose is 1 mg intravenously every 3 minutes.

Adrenaline is recommended as first-line therapy for ‘medical pacing’ for severe bradyarrhythmias that do not respond to atropine. Further details regarding cardiopulmonary resuscitation can be found in Chapter 30 .

Cardiogenic Shock

Catecholamine infusions may confer some advantages in cardiogenic shock, particularly in association with acute myocardial infarction. In patients with systolic heart failure, adrenaline, noradrenaline and dobutamine have beneficial short-term cardiovascular effects, although noradrenaline is currently regarded as a first-line drug.[43] However, there is no survival benefit when using any catecholamine.[34]

Milrinone and levosimendan may have a potential role in patients with diastolic heart failure, particularly those with associated high impedance states such as aortic stenosis and pulmonary hypertension. Due to their non-adrenergic mechanism of action, these agents may be useful in patients who are ‘resistant’ to catecholamines. There is no clinically important difference in outcomes in patients with cardiogenic shock who receive milrinone or dobutamine.[20]

Separation from cardiopulmonary bypass

Numerous combinations of vasoactive drugs have been used to wean patients from cardiopulmonary bypass. There are no definitive studies demonstrating the benefits of any specific catecholamine.

Adrenaline and noradrenaline have been found to increase cardiac output with little increase in heart rate or afterload and are often regarded as first-line drugs. Dobutamine may be associated with vasodilatation and hypotension.

There is no evidence that the catecholamines, including noradrenaline, cause vasospasm of arterial conduits in clinically used doses.

PDE inhibitors, such as milrinone and levosimendan, either as sole agents or in conjunction with adrenaline or noradrenaline, are administered in selected patients. In high-quality randomised clinical trials, no benefit in clinically important or patient-centred outcomes has been reported when using levosimendan or milrinone after cardiac surgery.[19], [44-46] Milrinone has been advocated in selected patients with high ventricular impedance states, such as in patients with pulmonary hypertension undergoing mitral valve replacement or in those with severe pre-operative diastolic heart failure.

Cardiopulmonary bypass may be associated with a systemic inflammatory response-type syndrome characterised by a transient hyperdynamic vasodilatory state. Noradrenaline is frequently given as a vasoactive drug in this context to restore mean arterial pressure.

Cerebral Perfusion Pressure

Augmentation of cerebral perfusion pressure is an important strategy in patients with pathological reductions in cerebral blood flow, such as traumatic brain injury and vasospasm after secured aneurysmal subarachnoid haemorrhage. Noradrenaline is frequently used to augment cerebral perfusion pressure but there is no conclusive evidence to recommend any drug over another.[7]

Liver failure

The use of terlipressin in patients with liver failure is based on trials with substantial methodological limitations. Terlipressin is superior to placebo but there are limited data comparing its use to noradrenaline.[47, 48] The use of synthetic agonists of V_1 in liver failure is detailed in Chapter 52 (Hepatic Failure).

Right Ventricular Failure

Right ventricular infarction and major pulmonary embolism may be associated with acute right ventricular failure. Right ventricular depression may also occur in severe sepsis. Restoration of preload is critical in these conditions, as the failing right ventricle is particularly susceptible to reductions in preload.

Vasoactive drugs, such as noradrenaline and adrenaline, are regarded as first-line drugs in these situations to maintain adequate mean arterial pressure so that right coronary artery perfusion is maintained.

Septic Shock

The cardiovascular effects of sepsis syndrome and septic shock are complex and range from an initial hyperdynamic vasodilatory state to one of increasing myocardial failure and paralysis of the peripheral vasculature (vasoplegia). The latter represents the inability of the venous circulation to respond to endogenous or exogenous catecholamines with resultant venous pooling.

An increasing body of literature now recommends the use of catecholamines as first-line agents in the treatment of septic shock. The Surviving Sepsis Campaign guidelines recommend noradrenaline as the first-line choice vasoactive drug, with a recent upgrade to a strong recommendation. [49] However, the basis for recommending noradrenaline over adrenaline is limited, with concerns about adverse metabolic and splanchnic side effects of adrenaline remaining unsubstantiated. [13]

There is no evidence supporting the use of dobutamine as a sole agent or in combination with noradrenaline in septic shock and its use adds little to the efficacy of noradrenaline or adrenaline in terms of resolution of shock or mortality. [50] There is no evidence to recommend the use of levosimendan in patients with sepsis. [17]

Vasodilators and antihypertensives

David O'Callaghan and David Benjamin Antcliffe

Vasodilators are a generic group of drugs that are primarily used in the intensive care unit (ICU) for the management of acute hypertensive states and emergencies. In addition, they have an important role in the management of myocardial ischaemia, systemic and pulmonary hypertension and cardiac failure. [1, 2]

Physiology

Blood pressure is controlled by a complex physiological neurohormonal system involving all components of the cardiovascular system. [3, 4] Clinical practice has focused on the arterial circulation as the major regulator of systemic pressure. The importance of venous circulation in determining mean arterial pressure and cardiac output is discussed in Chapter 23 .

The role of the peripheral vasculature in the regulation of blood pressure may be conceptually regarded as a balance between vasodilatation and vasoconstriction (Fig. 27.1). [4]

The flowchart presents interlinked pathways that regulate blood pressure through vascular endothelium signalling and the renin-angiotensin system. On the left, angiotensin-converting enzyme inhibitors enhance the conversion of arachidonic acid from its storage pool via phospholipase activation. Arachidonic acid then influences the endothelium to release P G I two, nitric oxide, and endothelin. P G I two and nitric oxide stimulate vasodilatation, assisted by beta agonists, calcium antagonists, sodium nitroprusside, and nitrates, resulting in decreased blood pressure. On the right side, angiotensinogen is converted to angiotensin one by renin. Angiotensin-converting enzyme then forms angiotensin two, which acts at three key points. It activates alpha sympathetic activity, leading to vasoconstriction. It stimulates aldosterone, increasing sodium reabsorption. It also interacts with I L six and N F kappa B to affect bradykinins. These processes result in increased blood pressure. Angiotensin-converting enzyme inhibitors, A two inhibitors, beta blockers, and diuretics act at different stages of the pathway to inhibit renin, aldosterone, or sodium retention. Inactive peptides and the degradation of bradykinins are also shown within the central region. The entire layout exhibits how multiple signals and pharmaceutical interventions affect vascular tone and systemic blood pressure.

FIG. 27.1 Schematic diagram of the neurohormonal factors determining vasomotor tone. Calcium Flux

The concentration of intracellular ionised calcium is the primary determinant of vascular smooth muscle tone; increases lead to smooth muscle contraction, while decreases cause relaxation. Control of calcium influx and efflux is determined by adrenergic receptor occupation and changes in membrane potential, which is mediated through voltage-gated channels (see Chapter 26 , Fig. 26.2).

Endothelial System

The endothelium plays a central role in blood pressure homeostasis by secreting substances such as nitric oxide (NO), prostacyclin and endothelin.[4] These substances are continuously released by the endothelium and are integral in regional autoregulation.[5] NO is synthesised from L-arginine by NO synthases and diffuses into smooth muscle where it activates guanylate cyclase to increase cyclic guanosine monophosphate (cGMP), resulting in the relaxation of underlying smooth muscle and vasodilatation. Prostacyclin is synthesised via the arachidonic pathway and has a minor role in the control of vascular tone, acting as a vasodilator. Endothelins are endothelium-derived vasoconstrictor peptides that are associated with increases in vascular smooth muscle intracellular calcium. They bind to endothelin receptors within the vascular smooth muscle, causing vasoconstriction,[6] usually in response to shear stresses, tissue hypoxia, angiotensin II and cortisol.[7]

Renin–Angiotensin–Aldosterone System

Angiotensinogen is converted by renin to form angiotensin I, which is subsequently converted to angiotensin II by the angiotensin-converting enzyme (ACE). Angiotensin II has numerous effects on blood pressure homeostasis, including the release of aldosterone, direct activation of α-adrenergic receptors on vascular smooth muscle and a direct effect on the endothelium. These effects are directed at maintaining blood pressure and are integral in the stress response. ACE also inactivates bradykinins that have predominantly vasodilatory effects, coupled with arachidonic acid synthesis and the generation of prostacyclin.

Adrenergic System

The sympathetic nervous system is integrally involved with all of the above systems, regulating vascular tone at central, ganglionic and local neural levels. Adrenergic stimulation of β-receptors is associated with vasodilatation; α-receptor stimulation results in vasoconstriction. The vascular effects of the catecholamines and vasopressors are discussed in Chapter 26 . Adrenergic stimulation is the predominant system regulating venous tone[8] via endothelial differences in veins resulting production of less NO and reduced responsiveness to angiotensin II.

Pathophysiology

Hypertensive states result from impaired or abnormal homeostatic processes, causing an imbalance between vasoconstriction and vasodilation. Essential hypertension is the most common cause of hypertension and is due to abnormal neurohormonal regulation, particularly exaggerated effects of renin–angiotensin activity. Secondary causes of hypertension include structural abnormalities such as aortic coarctation or renal artery stenosis; endocrine conditions such as phaeochromocytoma, Cushing syndrome and pregnancy-induced hypertension; and central causes such as raised intracranial pressure.

Calcium Channel Blockers

Calcium channel blockers have numerous effects on the cardiovascular system, influencing heart rate, myocardial contractility and vasomotor tone. The entry of calcium through voltage-gated calcium channels is a major determinant of arteriolar, but not venous, tone. [9] Calcium channel blockers are recommended as a first-step treatment for hypertension in Caucasian patients greater than 55 years and Afro-Caribbean patients of any age. [10] There are three major groups of calcium channel blockers that have different sites of action and therapeutic effects: dihydropyridines (e.g. nifedipine, nimodipine, nicardipine, amlodipine and felodipine), phenylalkylamines (e.g. verapamil) and benzothiazepines (e.g. diltiazem). Magnesium is a physiological calcium antagonist and is used therapeutically as magnesium sulphate.

Nifedipine

Nifedipine is a predominant arteriolar vasodilator, with minimal effect on venous capacitance vessels and no direct depressant effect on heart rate conduction. It may be administered intravenously, orally or sublingually and has a rapid onset of action of 2–5 minutes and a duration of action of 20–30 minutes. Nifedipine can be used to treat angina pectoris, especially due to coronary artery vasospasm. Peripheral vasodilatation results in decreased systemic blood pressure, often associated with sympathetic stimulation resulting in increased cardiac output and heart rate, which may counter the negative inotropic, chronotropic and dromotropic effects of nifedipine. Nevertheless, nifedipine may be associated with profound hypotension in patients with ventricular dysfunction, aortic stenosis and/or concomitant β-blockade. For this reason, the use of sublingual nifedipine as a method of treating hypertensive emergencies is no longer recommended.[11] Nifedipine and related drugs may cause diuretic-resistant peripheral oedema, which is due to the redistribution of extracellular fluid rather than sodium and water retention.

Nimodipine

Nimodipine is a highly lipid-soluble analogue of nifedipine. High lipid solubility facilitates entrance into the central nervous system where it causes selective cerebral arterial vasodilatation, which may attenuate cerebral arterial vasospasm following aneurysmal subarachnoid haemorrhage. Improved outcomes have been demonstrated in patients with Grade 1 and 2 subarachnoid haemorrhage.[12] Systemic hypotension may result from peripheral vasodilatation that may compromise cerebral blood flow in susceptible patients. Similarly, cerebral vasodilatation may increase intracranial pressure in patients with reduced intracranial elastance. The recommended dose following aneurysmal subarachnoid haemorrhage is 60 mg orally 4-hourly, but it can be given at 30 mg 2-hourly to reduce variation in blood pressure.

Amlodipine

Amlodipine is an oral preparation that has a similar pharmacodynamic profile to nifedipine. In addition to arteriolar vasodilatory and cardiac effects, amlodipine has been shown to exert specific anti-inflammatory effects in hypertension and diabetic nephropathy and in modulating high-density lipoprotein (HDL) in patients with hypercholesterolaemia.[13] These effects have seen amlodipine increasingly being used for the treatment of hypertension, and it may have a role in stable critically ill patients with associated comorbidities.

Verapamil

Verapamil predominantly affects the atrioventricular node and is principally used as an antiarrhythmic for the treatment of supraventricular tachyarrhythmias. For this reason, concomitant therapy with β-blockers or digoxin is not recommended. Verapamil is negatively inotropic and is not as active as nifedipine on smooth muscle; therefore it causes a less pronounced decrease in systemic blood pressure. It has a limited role as a vasodilator. [14]

Diltiazem

Diltiazem has a similar cardiovascular profile to verapamil, although its vasodilatory properties are intermediate between nifedipine and verapamil. Diltiazem exerts minimal cardiodepressant effects and is less likely to potentiate β-blockers.

Magnesium Sulphate

Magnesium regulates intracellular calcium and potassium levels by activating membrane pumps and competing with calcium for transmembrane channels. Physiological effects are widespread, affecting cardiovascular, central and peripheral nervous systems and the musculoskeletal junction. [15] It acts as a direct arteriolar and venous vasodilator, causing reductions in blood pressure. Modulation of centrally mediated and peripheral sympathetic tone results in variable effects on cardiac output and heart rate. Consequently, it has an established role in the treatment of pre-eclampsia and eclampsia, [16] perioperative management of phaeochromocytoma [17] and treatment of autonomic dysfunction in tetanus. [18] It has been proposed as a possible agent for the prevention of secondary ischaemia after aneurysmal subarachnoid haemorrhage; however, evidence of a benefit on outcome is still lacking. [19]

Direct-acting vasodilators

These drugs act directly on vascular smooth muscle and exert their effects predominantly by increasing the concentration of endothelial NO. These drugs are also known as nitrovasodilators. [20]

Glyceryl trinitrate

Glyceryl trinitrate is an organic nitrate that generates and causes vasodilation by acting as an NO donor. The pharmacokinetics allow glyceryl trinitrate to be given by infusion, with a longer onset and duration of action than sodium nitroprusside. The intravenous dosage can start at 0.3 mg/h and increase incrementally to a maximum dose of 20 mg/h. Glyceryl trinitrate may also be administered sublingually, orally or transdermally.

Tachyphylaxis is common with glyceryl trinitrate; doses should not be increased if patients no longer respond to standard doses. Glass bottles or polyethylene administration sets are required as glyceryl trinitrate is absorbed into standard polyvinylchloride sets.

The effects on the peripheral vasculature are dose dependent, acting principally on venous capacitance vessels to produce venous pooling and decreased ventricular preload. Glyceryl trinitrate primarily dilates larger conductance vessels of the coronary circulation, resulting in increased coronary blood flow to ischaemic subendocardial areas, thereby relieving angina pectoris.

Reductions in blood pressure are dependent on blood volume. Precipitous falls in blood pressure may occur in hypovolaemic patients with small doses of glyceryl trinitrate. At higher doses, arteriolar vasodilatation occurs without significant changes in calculated systemic vascular resistance.

Glyceryl trinitrate is a cerebral vasodilator and often causes headaches and should be used with caution in patients with known or suspected raised intracranial pressure.

Hydralazine

Hydralazine is a potent, arterioselective, direct-acting vasodilator that acts via the stimulation of cGMP and the inhibition of smooth muscle myosin light chain kinase. Following intravenous administration, 5–10 mg, hydralazine has a rapid onset of action, usually within 5–10 minutes. It can alternatively be given by continuous intravenous infusion, initially 12–18 mg/h with maintenance usually 3–9 mg/h. It may also be administered orally. The drug is partially metabolised by acetylation, for which there is marked inter-individual variability (35% of the population are slow acetylators). Although this does not have much clinical significance regarding the antihypertensive effects, it is important with respect to toxicity.[21]

Hydralazine causes predominantly arteriolar vasodilatation that is widespread but not uniform. Common indications for hydralazine include hypertensive emergencies in pregnancy and for controlling blood pressure in intracranial pathology, especially where bradycardia limits the use of labetalol. It is associated with direct and reflex sympathetic activity so that cardiac output and heart rate are increased. Prolonged use of hydralazine stimulates renin release and is associated with sodium and water retention. Consequently, hydralazine is frequently administered with β-blockers and/or diuretics.

Chronic use of hydralazine may be associated with immunological side effects including lupus syndrome, vasculitis, haemolytic anaemia and rapidly progressive glomerulonephritis.

Isosorbide Dinitrate

Isosorbide dinitrate is the most commonly administered oral nitrate for the prophylaxis of angina pectoris. It has a physiological effect that lasts up to 6 hours in doses of 30–120 mg. The mechanism of action is the same as glyceryl trinitrate. Hypotension may follow acute administration, but tolerance to this develops with chronic therapy.[21]

Nicorandil

Nicorandil has multiple actions. First, it is a potassium channel activator that leads to arteriodilation and improved coronary blood flow. Second, it has nitrate properties that cause venodilation and may also demonstrate cardioprotective effects against ischaemic injury. Nicorandil is currently indicated as a second-line treatment for stable angina, but its use may be limited by the main side effects of headache, flushing and ulceration.

Sodium Nitroprusside

Sodium nitroprusside is a non-selective vasodilator that causes the relaxation of arterial and venous smooth muscle. It is comprised of a ferrous ion centre associated with five cyanide moieties and a nitrosyl group. The molecule is 44% cyanide by weight and reconstituted sodium nitroprusside is light sensitive, so it requires protection from exposure to light. When infused intravenously, sodium nitroprusside interacts with oxyhaemoglobin, dissociating immediately to form methaemoglobin while releasing free cyanide and NO. The latter results in vasodilation.

Dosage is from 0.5 μg/kg/min to 8 μg/kg/min, but should always start at a low infusion rate and build up slowly. Large doses should not be used if the desired therapeutic effect is not attained, as this may be associated with toxicity.

Caution should be used with sodium nitroprusside in several clinical situations. Sodium nitroprusside may potentially increase myocardial ischaemia in patients with coronary artery disease by causing an intracoronary steal of blood flow away from ischaemic areas by arteriolar vasodilatation. Secondary tachycardia may also exacerbate myocardial ischaemia. In the cerebral circulation, sodium nitroprusside is a cerebral vasodilator, leading to increases in cerebral blood flow and blood volume. This may be critical in patients with increased intracranial pressure. Sodium nitroprusside is a pulmonary vasodilator and may attenuate hypoxic pulmonary vasoconstriction, resulting in increased intrapulmonary shunting and decreased arterial oxygen tension. This phenomenon may be exacerbated by associated hypotension.

Sodium nitroprusside toxicity can occur from either the production of cyanide or methaemoglobin. [22] A healthy adult can eliminate cyanide at a rate equivalent to a sodium nitroprusside infusion of 2 μg/kg/min or up to 10 μg/kg/min for 10 minutes, although there is marked inter-individual variability. Toxicity should be suspected in patients who become resistant to sodium nitroprusside despite maximum infusion rates and who develop unexplained lactic acidosis. In high doses, cyanide may cause seizures.

Treatment of suspected cyanide toxicity is cessation of the infusion and administration of 100% oxygen. Sodium thiosulphate (150 mg/kg) converts cyanide to thiocyanate, which is excreted renally. For severe cyanide toxicity, sodium nitrite may be infused (5 mg/kg) to produce methaemoglobin and subsequently cyanmethaemoglobin. Hydroxycobalamin, which binds cyanide to produce cyanocobalamin, may also be administered (5 g over 15 minutes, which may be repeated in severe cases).

Alpha-adrenergic antagonists

Several groups of compounds act as α-adrenergic blockers with variable affinity for populations of α-receptors. Physiology and pathophysiology may influence the responsiveness of the drug receptor–effector relationship. Receptor pathobiology is discussed in Chapter 26 . Consequently, there may be marked inter- and intraindividual variability in patient response to these drugs.

There are six main groups of α-receptor antagonists: imidazolines (e.g. phentolamine), haloalkylamines (e.g. phenoxybenzamine), prazosin, β-adrenergic antagonists with α-receptor antagonism (labetalol, carvedilol), phenothiazines (chlorpromazine) and butyrophenones (haloperidol).

Phentolamine

Phentolamine is a non-selective, competitive antagonist at α_1- and α_2-receptors. At low doses, phentolamine causes prejunctional inhibition of norepinephrine (noradrenaline) release (via α_2-receptor inhibition). At higher doses, a more complete α-receptor blockade is achieved, with enhancement of effects of β-agonists due to increased local concentration of norepinephrine produced by α_2-blockade (see Chapter 26 , Fig. 26.3A).

Phentolamine is administered intravenously in the management of hypertensive crises in the context of excess catecholamines released from pheochromocytoma and may be given intermittently or by infusion. Onset is rapid (within 2 minutes), with a duration of action of 10–15 minutes. Arteriolar and venous vasodilatation reduces systemic blood pressure. Effects on cardiac output are variable, and there is modest reflex sympathetic stimulation without significant increases in heart rate.

Phenoxybenzamine

Phenoxybenzamine is a non-selective, non-competitive, α_1- and α_2-receptor antagonist. Blockade is also produced on histamine, serotonin and acetylcholine muscarinic receptors. Reuptake of noradrenaline is blocked, thereby potentiating the effects of β-agonists. Phenoxybenzamine is usually administered orally but may also be given intravenously (taking care to avoid extravasation as it is an irritant to tissues). It has a long onset of action and a prolonged duration of action (3–4 days). It causes a gradual reduction in systemic blood pressure without rapid reflex sympathetic activity. Prolonged use is associated with increased β-adrenergic effects, predominantly increased heart rate, for which combination therapy with β-blockade is used. Phenoxybenzamine is primarily used in the management of phaeochromocytoma, either pre-operatively or long term in inoperable patients. It may also be used to control autonomic hyperreflexia in patients with spinal cord transection.[23]

Prazosin

Prazosin is a relatively arterioselective, competitive, α_1-receptor antagonist. It acts post-junctionally and therefore does not inhibit reuptake of norepinephrine. Consequently, it produces less tachycardia for a given reduction in systemic blood pressure. It is administered orally and is usually used for essential or renovascular (hyper-reninaemia) hypertension. It is frequently used in combination with β-blockers and diuretics, particularly in patients with renal dysfunction.

Labetalol

Labetalol is a specific competitive antagonist at α_1-, β_1- and β_2-adrenergic receptors. β-blockade effects predominate, with an approximate ratio of α_1:β-receptor blockade of 1:4–7. Labetalol has partial agonist effects on β_2-receptors. It is administered intravenously (typically 10–50 mg), has a rapid onset of action (5–10 minutes) with a duration of 2–6 hours. It may be given by infusion (usually 15–180 mg/h). Systemic blood pressure and cardiac output are reduced by a combination of negative inotropy, arterial and venous vasodilatation. These properties make labetalol particularly useful in controlled hypotension during anaesthesia and surgery to reduce bleeding. Side effects, such as bronchospasm and hyperkalaemia, relate predominantly to β-blockade.

Carvedilol

Carvedilol is a non-selective β-blocker with α_1-antagonist activity. Most of the vasodilator activity relates to α_1-antagonism, although at high concentrations, it also blocks calcium entry. The ratio of α_1:β-receptor blockade is 1:10. It is administered orally; no intravenous preparation is available. Studies have demonstrated the slowing of the progression of congestive cardiac failure and improved mortality, particularly when used in conjunction with ACE inhibitors in patients with mild to moderate cardiac failure.[24,25] It may also be used in patients who cannot be treated with ACE inhibitors.

Haloperidol and Chlorpromazine

These drugs act as competitive α-receptor antagonists causing non-selective vasodilatation and blockade of noradrenaline reuptake. These drugs are primarily used as major tranquillisers or antipsychotics; their effect on the peripheral vasculature should be regarded as a side effect rather than a specific therapeutic action. Reduction of systemic blood pressure is variable and may be precipitous, particularly in hypovolaemic patients with high sympathetic drive. These drugs may be useful in neurogenic hypertension and are not regarded as first-line vasodilators.

Inodilators

Many inotropic drugs have peripheral vascular effects, and these are discussed in more detail in Chapter 26 . At low doses, adrenaline, noradrenaline and dopamine are predominantly β-agonists and can cause both arterial and venous vasodilatation. The response depends on tissue receptor predominance and density. For example, in skeletal muscle, adrenaline causes vasodilation, whereas in subcutaneous tissue, it is a potent vasoconstrictor; it is for this reason that intramuscular adrenaline is administered in anaphylaxis (the skeletal muscle vasodilation causing rapid systemic absorption) whereas subcutaneous administration will result in little systemic effect.

Dobutamine and isoprenaline are predominantly β-agonists and may cause decreases in mean arterial pressure, particularly in hypovolaemic patients or those with increased sympathetic drive. These agents may have a role in reducing left ventricular afterload in patients with systolic heart failure. The inodilators milrinone and levosimendan are covered in Chapter 26 .

Angiotensin-Converting Enzyme Inhibitors

ACE inhibition has become a cornerstone in the management of patients with hypertension, cardiac failure and ischaemic heart disease. [26] , [27] They are now recommended as first-stage treatment for hypertension in Caucasian patients aged less than 55 years and patients with type 2 diabetes. [10] These drugs act by non-selective, competitive, irreversible inhibition to the angiotensin I binding site thus reducing conversion to angiotensin II. There are a very large number of ACE inhibitors on the market with very high penetration into the ambulant patient population. These drugs are administered orally; there are no routinely used parenteral preparations. Consequently, many critically ill patients admitted to the ICU may be taking ACE inhibitors. As a general rule, ACE inhibitors are stopped in most critically ill patients until vital organ (specifically renal) function is stabilised and the patient can take them enterally. Thereafter, doses are gradually increased over time with close monitoring of renal function.

Preparations

Captopril has a short half-life and therefore may be useful for initiating treatment within the ICU. It is administered orally in increasing doses and intervals to a maximum dose of 50 mg 8-hourly. It may be administered sublingually in acute hypertension (5–25 mg), with an onset of action in 20–30 minutes, and a duration of 4 hours. There are no significant differences in the cardiovascular effects between captopril and other preparations.

Enalapril and ramipril are prodrugs, activated by hepatic metabolism to enalaprilat and ramiprilat respectively. They are both administered orally. Enalapril can be increased in 5 mg increments to a total of 20 mg twice daily and ramipril is given initially at a dose of 1.25–2.5 mg and increasing to 10 mg once a day.

As with ramipril, lisinopril has the advantage of single daily dosing and may be useful in stable critically ill patients.

Cardiovascular Effects

The cardiovascular effects of ACE inhibition are widespread, with effects that influence the peripheral vasculature, cardiac performance and salt and water homeostasis. Consequently, ACE inhibitors are not principally regarded as vasodilators, although they have both direct and indirect effects on the peripheral vasculature.

Increased production of endothelial vasodilators, such as prostacyclin and decreased production of endothelin by angiotensin result in generalised venous and arteriolar vasodilatation. This occurs in the absence of reflex sympathetic activity or changes in heart rate, due to the modulation of adrenergic stimulation. Systemic blood pressure is reduced without changes in cardiac output or heart rate.

ACE inhibition is associated with improved myocardial performance following acute myocardial infarction due to left ventricular remodelling and improvement in neurohumoral activation. These drugs have been shown to improve survival following myocardial infarction in patients with left ventricular dysfunction.[28]

‘First-dose hypotension’ is described in patients receiving ACE inhibitors for the first time. This may occur particularly in patients who are salt- and water-depleted or those who develop sensitivity to the drug. Drug sensitivity may also present as a sudden decrease in renal function following the commencement of the drug.

Renovascular Effects

ACE inhibitors may cause renal failure, particularly in patients with renovascular disease, hyper-reninaemic hypertension and acute kidney injury. The renal effects of ACE inhibitors may be potentiated by diuretics, non-steroidal anti-inflammatory drugs and β-blockers. ACE inhibitors are contraindicated in patients with bilateral renal artery stenosis. As a rule, in intensive care patients, ACE inhibitors are started in suitable patients once the renal function has stabilised and the patient no longer requires inotropic support. Initial doses should be low and increased as tolerated.

Side Effects and Toxicity

In addition to renal dysfunction, ACE inhibitors may be associated with a number of side effects. The most common of these is cough, which is due to the increased production of kinins.[29] Severe angioneurotic oedema causing upper-airway obstruction may occur with all ACE inhibitors, although this is less common with enalapril and lisinopril. This is due to the increased activation of bradykinins. ACE inhibitors are contraindicated in patients with a history of hereditary or idiopathic angioneurotic oedema.[30] Neutropenia and agranulocytosis are uncommon but potentially lethal side effects in susceptible patients. ACE inhibitors should be avoided in pregnancy due to the potential risk of foetal malformation and renal impairment.

Angiotensin Receptor Blockers

These are a class of antihypertensive drugs that cause irreversible, selective blockade of angiotensin II at AT_1 receptors.[31,32] Losartan was the prototype, which has been followed by newer compounds such as irbesartan, valsartan and telmisartan. These drugs are oral preparations; there is no parenteral form. The cardiovascular profile of angiotensin receptor blockers is similar to the ACE inhibitors, but selective blockade of angiotensin II offers several possible advantages over ACE inhibitors. These drugs are long acting and may be given once daily; onset of action is slow, thereby avoiding first-dose hypotension; and side effects, such as cough and angioneurotic oedema, are less common.[33] Angiotensin receptor blockers may be used as an alternative to ACE inhibitors, and are recommended in preference to ACE inhibitors in patients with hypertension who are of Black African or African–Caribbean family origin, but they should not be combined.[10]

Centrally Acting Agents

These agents modulate adrenergic stimulation at the central nervous system and spinal cord levels. The vasomotor centre of the medulla mainly controls sympathetic pressor influences, although other brainstem, midbrain and spinal centres have a role. Most central responses are mediated through α_2-adrenergic receptors, which modulate the release and reuptake of noradrenaline, with subsequent effects on the peripheral vasculature and cardiac function.

Clonidine

Clonidine is a centrally acting α_2-agonist that stimulates inhibitory neurons in the vasomotor centre. This results in a reduction in sympathetic outflow from the central nervous system and is associated with negative inotropy and a reduction in heart rate. Systemic blood pressure is reduced by this mechanism, with associated arteriolar and venous vasodilatation. Clonidine has centrally acting analgesic properties, which make it a suitable drug for patients with postoperative hypertension. Peripherally, it stimulates prejunctional α_2-receptors, thereby decreasing norepinephrine release, but it may also have an effect on postjunctional α_1-receptors, causing vasoconstriction. This may present as rebound hypertension following an initial reduction of blood pressure as there is variable duration of the central and peripheral effects. When used for its hypertensive effects, clonidine is usually administered orally (50–100 µg 8-hourly). It has a rapid onset of action and a duration of action of 20–30 minutes.

Methyldopa

Methyldopa acts as a centrally acting ‘false’ transmitter following metabolism to methylnorepinephrine and subsequent stimulation of α_2-receptors leading to reduced sympathetic outflow, although the precise mechanism is not clear. It has a limited role in hypertensive emergencies but is useful in accelerated essential, renovascular and pregnancy-induced hypertension. It is administered orally in doses of 250 mg to 3 g per day, although side effects (e.g. drowsiness and depression) may be minimised if the daily dose is less than 1 g. It may lead to a positive direct Coombs test in 10%–20% of patients.

Other antihypertensive agents

Beta-Adrenergic Antagonists

β-blockers have been used for the treatment of hypertension for over 30 years and have an increasingly important role in the management of cardiac failure.[34–36] Although no longer recommended as first-line treatment of hypertension, they may be initiated in the community as a fourth-line therapy especially if blood potassium is >4.5 mmol/L.[10] In addition to decreasing heart rate and contractility, β-blockers have other neurohumoral effects that affect vascular tone. These relate to the inhibition of renin release from juxtaglomerular cells (see Fig. 27.1) and prejunctional inhibition of noradrenaline, which results in a reduction in vascular tone and blood pressure. A central effect of β-blockers has also been proposed.

The mode of action has been described in terms of selectivity to blockade of β-adrenergic receptors (β_1 and/or β_2). While this is an appropriate pharmacological distinction, the clinical activity of these drugs is not as predictable due to mixed populations of β_1- and β_2-receptors in most organs and variable receptor responsiveness in physiological and pathophysiological conditions. Consequently, there is marked inter-individual variability in the response to these drugs. In high-enough doses, whether intentionally or due to toxicity, all β-blockers will cause generalised antagonism with resultant therapeutic and toxic effects.

Lipid-soluble β-blockers include propranolol and metoprolol, which are predominantly excreted by the liver; atenolol and sotalol are water-soluble and predominantly renally excreted, warranting caution with these drugs in patients with renal dysfunction.

β-blockers may be given orally or intravenously. As there is significant first-pass metabolism, doses for oral and intravenous administration are markedly different. Esmolol is an intravenous β-blocker that is rapidly metabolised by red cell esterases and is therefore not dependent on renal or hepatic function. Its rapid onset of action and short duration allow infusion of the drug, making it a useful drug in patients with acute hypertensive states associated with tachycardia. Labetalol and carvedilol are discussed previously.

β-blockers are frequently used as adjuncts to vasodilators in the treatment of hypertensive emergencies and states, particularly where reflex tachycardia and sympathetic stimulation occur (e.g. hydralazine, nifedipine and prazosin).

Side effects and toxicity of β-blockers include bradycardia (which may be profound), hypotension, bronchoconstriction (caution in patients who have asthma), aggravation of peripheral vascular ischaemia, hyperkalaemia and masking of the sympathetic response to hypoglycaemia.

Diuretics

As with β-blockers, diuretics have an established place in the management of hypertension. In addition to their effects on salt and water excretion and the inhibition of aldosterone, direct vasodilatory effects are associated with diuretics such as frusemide and thiazides. These drugs have a rapid venodilatory action, which may be due to the inhibition of noradrenaline-activated chloride channels in veins. Reductions of blood pressure and right atrial pressure may occur following low doses and may present before an associated diuresis. All diuretics should be used with caution in patients with renal dysfunction and avoided if hypovolaemia is present or suspected.

Pulmonary Vasodilators

Pulmonary vasodilators may be used in the ICU mainly to treat acute right-sided heart failure, commonly after cardiac surgery/transplantation. Many of the systemic vasodilators (namely calcium channel blockers, sodium nitroprusside and nitrates) will also have vasodilatory effects within the pulmonary circulation. Specific pulmonary vasodilators may be inhaled or administered intravenously.

Nitric Oxide

NO is an endogenous vasodilator. When inhaled it leads to vasodilation in only the ventilated areas of the lung, and rapid combination with haemoglobin and conversion to an inactive form prevents systemic vasodilation. This may improve ventilation–perfusion mismatch, resulting in improved oxygenation, but controlled trials have not demonstrated any beneficial effect on outcomes in severe acute lung injury and it may have an adverse effect on kidney function. [37] Its use is now mainly confined to the treatment of acute pulmonary hypertension post-cardiac surgery. NO is oxidated to NO_2, particularly in a high-oxygen environment. NO_2 causes pulmonary toxicity and therefore NO_2 levels should be carefully monitored and an appropriate scavenging system should be employed. Rebound pulmonary hypertension may occur, so NO therapy should be slowly weaned rather than abruptly stopped.

Prostacyclin

Inhaled epoprostenol or iloprost (a prostacyclin derivative) can be used as alternatives to NO; however, although some short-term benefit in oxygenation may be seen there is currently no evidence of improved outcomes with this therapy. [38] Care should be taken to avoid systemic hypotension.

Sildenafil

Sildenafil is a phosphodiesterase type 5 inhibitor used in the management of chronic pulmonary hypertension as well as erectile dysfunction. There are reports of its use for acute pulmonary hypertension within the ICU where it can improve haemodynamics; however, increasing shunt fraction it might worsen oxygenation when used in acute lung injury. [39]

Bosentan

Bosentan is a non-selective endothelin receptor antagonist. Its predominant use is in the treatment of type 1 pulmonary hypertension, where it improves exercise capacity and delays clinical worsening. Currently, bosentan has no established role in critical care.

Drug Selection

The clinical use of vasodilators in intensive care is different from their use in ambulatory patients. In critically ill patients, these drugs are primarily used to control acute rises in mean arterial pressure associated with sympathetic stimulation, or as specific treatment of hypertensive emergencies. [40] The ideal vasodilator is therefore one that has a rapid and predictable onset of action, allows titration to achieve the desired systemic blood pressure, does not compromise cardiac output, does not cause significant reflex tachycardia and is non-toxic. The selection of drugs to treat hypertensive states will depend on the predominant cause of hypertension and the mechanism of action in the homeostatic pathway (outlined in Fig. 27.1).

There are no large studies investigating optimum therapy in patients presenting with hypertensive emergencies. These conditions occur in a heterogeneous group of patients and drug selection is essentially determined by the underlying pathophysiology, personal preference and experience. [40]

Monitoring

The principles of haemodynamic monitoring in patients receiving vasoactive drugs are outlined in Chapter 24 . As peripheral vasodilators have significant effects on both the arterial and venous systems, the assessment of volume status is important. In the majority of patients, establishing a euvolaemic state is essential before commencing a vasodilator.

Dosages and Drug Administration

Vasodilators administered via infusion are delivered through a dedicated central venous catheter using infusion pumps or syringe drivers and are titrated to achieve a target mean or systolic arterial pressure. Infusion lines should be free of injection portals and clearly marked with identifying labels. Common drug doses are shown in Table 27.1 .

Table 27.1

Dose and infusion concentrations of commonly used vasodilators and antihypertensives in intensive care

AGENT	INFUSION/DOSE	CAUTION
Sodium nitroprusside	Diluted in 5% dextrose; range 0.5–8 μg/kg/min	Cyanide toxicity (>total dose 0.5 mg/kg/24 h) Photodegradation Raised intracranial pressure Rebound hypotension Shunt and oxygen desaturation
Glyceryl trinitrate	Diluted in 5% dextrose or 0.9% sodium chloride; range 5–200 μg/min	Drug binding to polyvinylchloride Tachyphylaxis Raised intracranial pressure
Hydralazine	5–10 mg IV bolus IV infusion 50–150 μg/min	Tachycardia Myocardial ischaemia
Phentolamine	1–5 mg IV boluses	Tachycardia
Phenoxybenzamine	Oral: 10 mg/day until postural hypotension	Idiosyncratic hypotension
Prazosin	500 μg, 8-hourly up to 20 mg daily in divided doses	
Nifedipine	Dose depends on the preparation	Precipitous hypotension

AGENT	INFUSION/DOSE	CAUTION
Amlodipine	5–10 mg oral/day	
Captopril	6.25–75 mg orally, 12-hourly	Caution in renovascular hypertension and renal failure Pregnancy Angioneurotic oedema
Enalapril	5–40 mg oral/day	Caution in renovascular hypertension and renal failure Pregnancy Angioneurotic oedema
Ramipril	1.25–10 mg oral/day	Caution in renovascular hypertension and renal failure Pregnancy Angioneurotic oedema
Losartan	25–100 mg oral/day	Caution in renal failure
Clonidine	50–100 µg 8-hourly	May cause rebound hypertension with chronic use
Atenolol	25–50 mg oral b.d.	Caution in poor left ventricular function and asthma Hyperkalaemia Effects potentiated in renal failure
Metoprolol	50–100 mg oral 12-hourly	As for atenolol, safe in renal failure
Bisoprolol	1.25–20 mg oral/day	As per metoprolol

AGENT	INFUSION/DOSE	CAUTION
Esmolol	50–200 μg/kg/min infusion	
Labetalol	15–160 mg/h	

IV , Intravenous.

Specific situations

The following is a summary of the clinical uses of the above drugs in hypertensive states commonly encountered in the ICU. Specific pharmacology and physiological effects are discussed previously.

Acute Hypertension

The most common cause of hypertension in intensive care patients is pain or agitation, particularly in postoperative patients. It is important that patients have adequate analgesia and sedation before antihypertensives or vasodilators are used. Other common causes of hypertension include hypothermia, urinary retention, positional discomfort and omission of pre-admission antihypertensives, particularly β-blockers and ACE inhibitors. The majority of instances of acute hypertension in the ICU will respond to simple measures.[41]

Sustained hypertension may be treated acutely with incremental doses or infusions of short-acting drugs such as glyceryl trinitrate, labetalol, hydralazine, nicardipine, nitroprusside or clonidine. Infusions of vasodilators may be required if hypertension persists or if the patient is unable to take longer-acting oral agents such as prazosin or amlodipine. Hypertension associated with tachycardia may be treated with β-blockers.

A hypertensive emergency is an acute rise in blood pressure, usually greater than 180 mm Hg systolic or greater than 110–120 mm Hg diastolic, although there is no defined threshold, which is associated with signs of end-organ damage. Commonly affected organs include the brain (seizures, hypertensive encephalopathy), heart (pulmonary oedema and acute coronary syndromes), kidney, great vessels (aortic dissection) and retina (papilloedema and retinal haemorrhages). A similar rise in blood pressure not associated with end-organ damage is known as severe asymptomatic hypertension or a hypertensive urgency.[42] In hypertensive emergencies a priority is the rapid control of blood pressure over minutes to hours with a recommendation of a maximal reduction of 20% to 25% during the first hour and then to 160/100 to 110 mm Hg during the ensuing 2 to 6 hours.[42] Alternatively, in severe asymptomatic hypertension rapid management of blood pressure is often not required and may be harmful. In this situation, blood pressure reduction is less urgent and may be achieved over days in an ambulatory setting.[42]

Patients with hypertensive emergencies are frequently hypovolaemic due to excessive sympathetic stimulation. In the absence of left ventricular failure, judicious fluid replacement may reduce blood pressure and improve renal function, thereby minimising precipitous hypotension that may result following the administration of some drugs. Diuretics are generally avoided in these conditions unless there is evidence of left ventricular failure.[42]

Hypertensive Encephalopathy

Hypertensive encephalopathy is the presence of signs arising from cerebral oedema caused by a rapidly changed or severely elevated blood pressure. There may be differences in the degree of hypertension that cause encephalopathy, and it may be the rate of increase of blood pressure that is more important than the absolute value. It may present as confusion, visual disturbances, blindness, seizures or stroke. Uncontrolled hypertension is one of the causes of posterior reversible encephalopathy syndrome (PRES), along with pre-eclampsia, autoimmune diseases and immunosuppressant drugs. If not adequately treated, hypertensive encephalopathy may result in intracerebral haemorrhage, coma or death.[43]

Hypertensive encephalopathy may occur in patients with untreated or undertreated hypertension or in association with other diseases such as renal disease (e.g. glomerulonephritis, renovascular disease), thrombotic thrombocytopenic purpura, immunosuppressive therapy, collagen vascular diseases or eclampsia. Consequently, drug treatment will depend on the context in which it occurs. It is also important to rule out other causes of neurological deterioration that may also present with hypertension (e.g. stroke, intracranial haemorrhage or space-occupying lesion).

There is no evidence from randomised controlled trials to conclude that one therapy is superior to another at improving outcomes. The aim of drug therapy in these patients is to reduce blood pressure in a controlled, predictable and safe way. A blood pressure reduction of 20% to 25% of the mean arterial pressure should be a goal.[44] Acutely, short-acting, titratable parenteral drugs are suitable in emergency situations. Current guidelines recommend the use of labetalol or nicardipine as first-line agents for the treatment of hypertensive encephalopathy with sodium nitroprusside as a second-line agent.[44]

Acute Stroke

Acute stroke syndromes frequently occur in the setting of severe hypertension. The reduction of mean arterial pressure must be balanced by the maintenance of adequate cerebral perfusion pressure and cerebral blood flow. Ischaemic brain is vulnerable to critical reductions in cerebral blood flow, while excessive mean arterial pressure may increase the risk of cerebral haemorrhage.[45]

Acutely, blood pressure should be maintained in a normal range until intracranial pathology has been identified by computed tomography scan. Evidence is currently lacking regarding specific targets for blood pressure control in acute stroke. In intracranial haemorrhage intracranial pressure monitoring may be necessary to allow blood pressure to be targeted at maintaining cerebral perfusion pressure; however, if presenting systolic pressure is 150–220 mm Hg reduction to <140 mm Hg is probably safe.[46,47] In acute ischaemic stroke, special attention needs to be paid to patients who may be eligible for thrombolysis. In these patients, treatment is recommended to reduce systolic blood pressure to less than 185 mm Hg and diastolic pressure to less than 110 mm Hg prior to thrombolysis.[47] In those who do not meet the criteria for thrombolysis blood pressure reduction is generally not recommended. However, in cases where the blood pressure is greater than 220 mm Hg systolic or 120 mm Hg diastolic, there may be a role for blood pressure reduction, although the benefit is uncertain. [48] Where acute blood pressure reduction is necessary intravenous agents are recommended. Hypertension in patients with aneurysmal subarachnoid haemorrhage is managed with drugs outlined previously.

Aortic Dissection

Aortic dissection is the most dramatic and most rapidly fatal complication of severe hypertension. The aim of medical treatment is to control blood pressure and left ventricular ejection velocity to minimise the propagation of the dissection. Blood pressure should be decreased as rapidly as possible to a normal or slightly hypotensive level. Titrations are usually made to achieve systolic blood pressures of <120 mm Hg, or to the lowest blood pressure that maintains end-organ perfusion, with a heart rate of 60–80 bpm. [49], [50] This will depend on the patient's pre-morbid blood pressure and the accuracy of blood pressure measurement. It is important to maintain blood pressure at levels compatible with adequate cerebral and renal perfusion. [51]

This is best achieved initially by the use of opioid analgesia and intravenous β-blockers (e.g. esmolol, labetalol or metoprolol). Non-dihydropyridine calcium channel inhibitors such as verapamil or diltiazem are suitable alternatives for patients who have a contraindication to β-blockade. Second-line therapy may be with a vasodilator such as sodium nitroprusside or nicardipine. However, the use of vasodilators alone should be avoided as this is associated with compensatory tachycardia, worsening aortic wall shear stresses and potential worsening of the dissection.

Aortic dissection distal to the left subclavian artery is managed conservatively with antihypertensive therapy (see Chapter 35). Proximal dissections are managed surgically after acute control of blood pressure.

Acute Myocardial Ischaemia

Myocardial ischaemia in the absence of obstructive coronary atherosclerosis may be precipitated by severe hypertension. This occurs through increased left ventricular wall stress, reduced preload, tachycardia and increased myocardial metabolic demand. Ischaemia may precipitate acute left ventricular failure and pulmonary oedema. [52] Affected patients should receive a loop diuretic in combination with a titrated vasodilator, such as intravenous glyceryl trinitrate or sodium nitroprusside, to reduce afterload. [53] Beta blockade may be indicated in patients receiving nitroglycerine, particularly when heart rate is elevated. [53]

Phaeochromocytoma

Tumours of the adrenal medulla secrete catecholamines that result in initial paroxysmal, then sustained, severe hypertension. They may present to the ICU as a hypertensive emergency or perioperatively for surgical ablation. [54]

Acute hypertensive crises associated with phaeochromocytoma are managed with incremental doses or infusions of phentolamine. Untreated patients can be hypovolaemic and may require volume replacement. β-blockers should not be used in the acute setting as these will potentiate unopposed α-adrenergic stimulation.

Preparation for surgery involves initiating alpha-adrenergic blocking agents as first-line therapy to prevent cardiovascular complications. Calcium channel antagonists may be added to improve blood pressure control. [55] Excessive β-adrenergic effects are treated with β-blockers only after α-blockade to avoid unopposed α-adrenoreceptor-mediated vasoconstriction and hypertension. [23]

Alpha-methyl paratyrosine (metyrosine) inhibits catecholamine synthesis and may be used as a short-course therapy, in combination with alpha-adrenergic blocking agents, in the lead-up to surgery to help stabilise blood pressure. [55]

Renal Failure

Renal insufficiency may be a cause or consequence of a hypertensive emergency. Patients on haemodialysis (particularly those receiving erythropoietin therapy) and renal transplant patients (especially those receiving ciclosporin or corticosteroids) commonly present with severe hypertension. Patients with chronic kidney disease (CKD) should receive lifestyle advice and sodium restriction. Drug treatment is titrated toward achieving a systolic of 140 mm Hg or less and a diastolic of 90 mm Hg. [56] Achieving recommended blood pressure targets in CKD often requires combination therapy. This should be initiated as a combination of renin–angiotensin system blocker with a calcium channel blocker or diuretic. [56]

In patients with new-onset renal failure accompanying severe hypertension, blood pressure must be controlled without potentiating renal dysfunction. Drugs, such as calcium channel blockers, phentolamine or prazosin, may preserve renal blood flow and are appropriate in these patients. ACE inhibitors and diuretics should be used with caution until renal function has stabilised or improved.

Patients in the recovery phase of acute renal failure are usually hypertensive. This is a normal physiological response and should not be treated unless there is associated myocardial or cerebral ischaemia. [57]

Pre-Eclampsia and Eclampsia

In addition to delivery of the baby and the placenta, parenteral magnesium sulphate should be given if a woman with severe hypertension or pre-eclampsia has previously had an eclamptic fit. [58] Magnesium should also be considered in a critical care setting for those women with severe pre-eclampsia when delivery is planned within 24 hours and in those with more than one feature of severe pre-eclampsia. The recommended drugs for the treatment of severe hypertension in critically ill women during pregnancy or soon after birth are labetalol (PO or IV), hydralazine (IV) and nifedipine (PO). [58]

Some brands of nifedipine are contraindicated by the manufacturer in pregnancy, so individual product characteristics should be consulted prior to administration. [58]

ACE inhibitors and angiotensin receptor blockers are contraindicated in pregnancy. This is discussed in Chapter 89 .

Drug Interactions

Severe rebound hypertension may result following abrupt cessation of antihypertensive treatment. Drugs associated with this discontinuation syndrome include clonidine, methyldopa, β-blockers, guanethidine and diuretics. The degree of rebound depends on the rapidity of drug withdrawal, dosage, renovascular and cardiac function. Antihypertensives should be reintroduced according to the status of the patient, and the degree of hypertension should be managed accordingly.

Interaction between monoamine oxidase inhibitors, other drugs (e.g. indirect sympathomimetics and narcotics) and tyramine-containing foods may result in a hypertensive emergency. This is best managed acutely with α- and/or β-blockers.

Mechanical cardiac supports

Vince Pellegrino, Julia Coull and Brooke Riley

Introduction

Mechanical cardiac support (MCS) devices are designed to provide short-, intermediate- and long-term haemodynamic support for a variety of pathological conditions. Their applications range from provision of prophylactic support for high-risk procedures, acute management of cardiogenic shock (CS), bridge-to-transplant and time-critical deployment in cardiac arrest (CA).

CS accounts for approximately 28% of all non-traumatic shock presentations to emergency departments.[1] Despite advances in medical and mechanical haemodynamic support, patients with CS have a 30-day mortality of approximately 40% and 1-year mortality approaching 50%.[2,3]

An increasing number of short-term MCS devices have been developed and this has led to increased use over the last 15 years. The available devices vary in their pump mechanism and ability to provide left- and/or right-sided support.[4] These MCS devices increase the complexity and potential complications associated with the management of CS. There is building evidence that treatment at higher-volume centres and with high-volume operators is linked to improved outcomes.[3,5]

Specific Patient Populations

CS occurs due to a wide number of disorders with the cardiac insult resulting in the onset of acute or acute-on-chronic ventricular dysfunction.

The indications for and utilisation of MCS in patients with CS vary due to heterogeneity in aetiology, clinical manifestations, and background characteristics of the patient populations. Although there is currently a paucity of robust evidence supporting the use of MCS devices, there is a group of patients who are unresponsive to conventional intensive care management, where the use of MCS devices may be their only chance for survival.

It is crucial to adopt a multidisciplinary team-based approach to the assessment of patients for MCS. If time permits, a considered evaluation should occur prior to the commencement of support, including the identification of expected end points and exit pathways. Patients with reversible pathologies such as myocarditis, postpartum cardiomyopathy and toxidromes are ideal candidates for MCS as a bridge-to-recovery. Patients with chronic end-stage pathologies, such as ischaemic cardiomyopathy, primary pulmonary hypertension and congenital cardiac disease, are less likely to recover in the event of acute decompensation; their recovery is linked to implantation of long-term MCS (bridge-to-device) or organ transplantation (bridge-to-transplant).

In patients with CS or CA where the pathology or past history is unknown, MCS commencement can be used as a bridge-to-assessment or bridge-to-decision.

Acute Myocardial Infarction-Related CS

Acute myocardial infarction (AMI) is the predominant aetiology resulting in CS, with ST-elevation AMI (STEMI) accounting for almost 70% of this patient subgroup.[6,7] Mechanical complications of AMI such as papillary muscle rupture, ventricular septal defect and LV free wall rupture were responsible for appropriately 20% of AMI-related CS cases.[6] Early revascularisation remains the gold-standard therapy for AMI-related CS.[8] In the SHOCK trial and registry, 78.5% of AMI-related CS cases were associated with predominant LV failure.[9]

Acute Decompensated Heart Failure (ADHF)

Non-AMI causes account for approximately 20% of CS cases and encompasses a span of aetiologies. [6] Acute decompensation of chronic heart failure makes up almost 50% of this group, with valvular and mechanical causes causing approximately 30%, stress cardiomyopathy and myocarditis account for 10% of cases each. [6]

Post-Cardiotomy Shock

CS that develops post cardiothoracic surgery is defined as post-cardiotomy shock and it affects 1%–6% of cardiac surgical cases. [10] In contrast to AMI-related CS, up to 40% of this population present with echocardiographic evidence of right ventricular (RV) dysfunction. [11] Management of this CS population is especially challenging owing to the multifactorial nature of the underlying pathophysiology, which combines local surgical damage, ischaemia-reperfusion injury, vasodilation and haemorrhage. [7], [11]

Obstructive Shock

Patients with obstructive shock resulting from acute pulmonary embolism have a high mortality if requiring CPR or mechanical ventilation. [12] The increase in pulmonary vascular resistance from acute pulmonary embolism can provoke RV decompensation, with a reduction in stroke volume, RV dilatation and an alteration of ventricular interdependence. [13] The timing of MCS in this group is crucial, with a significant increase in 30-day mortality when patients deteriorate to CA. [14]

Timing of Mechanical Cardiac Support

The wide variety of indications for initiation of MCS combined with diverse clinical presentations of the disease make it challenging to pinpoint the optimal timing for initiation of support. There are a few key general principles that should be applied to the individual clinical scenario to help guide treatment.

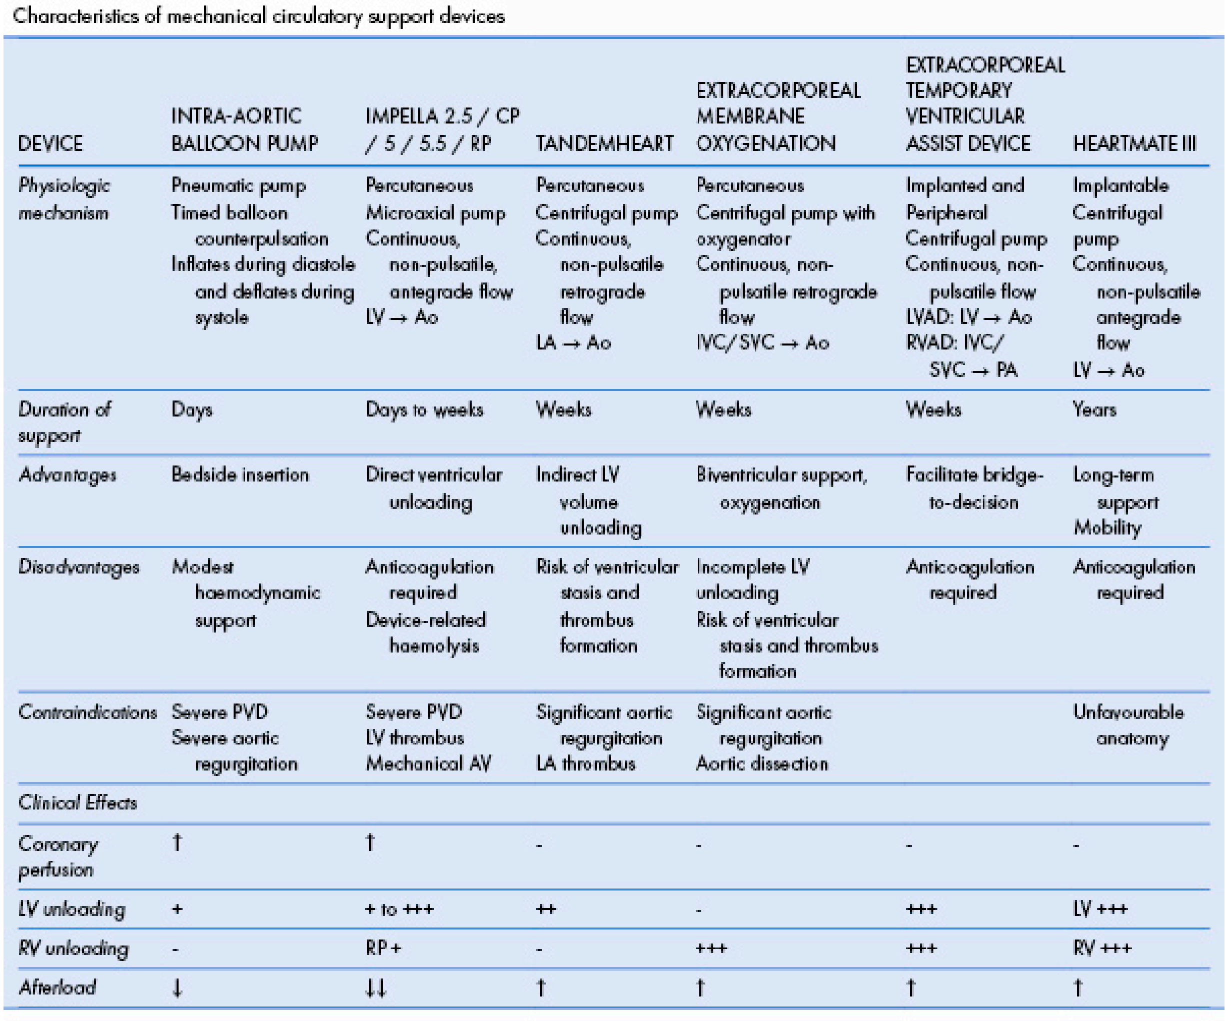
Inotropes and vasopressors are regarded as first-line therapies for CS, however, there is a lack of data showing mortality benefit and potential harm associated with increasing inotropes/vasopressors due to coronary and peripheral vasoconstriction leading to irreversible end-organ injury.[7, 15] Early initiation of MCS may avoid some of these detrimental effects by augmenting cardiac output and decreasing medications associated with increased myocardial oxygen demands, however, premature initiation of MCS may subject patients to unnecessary risk.[15] There is emerging evidence that early MCS initiation prior to revascularisation may be beneficial due to the effects of mechanical unloading and reduced reperfusion injury, however, there is a dearth of strong evidence to support this practice at present.[7, 16] Scoring systems such as the SAVE-score for application of V-A ECMO in refractory CS may be helpful in guiding decision making.[17] An artificial intelligence (AI) algorithm, ECMO prediction algorithm (ECMO-PAL), has recently analysed retrospective data from the extracorporeal life support organisation (ELSO) to determine in-hospital mortality for V-A ECMO patients. ECMO-PAL outperformed currently used scoring systems and highlighted the future of AI and ECMO.[18]

MCS provides minimal patient benefit if commenced after established multi-organ failure, microcirculatory failure, and peripheral ischaemia. Therefore early recognition of inadequate circulatory support or single organ failure is crucial for patient outcomes. Moderate or high dose inotropes (adrenaline >0.2 mcg/kg/min equivalent), with inadequate cardiac output or blood pressure, rising lactate (>5 mmol/L), declining urine output or elevated liver function tests should prompt assessment for MCS.

Mechanical cardiac support devices

Multiple factors influence the decision making regarding the most appropriate MCS device for an individual patient's presentation. Pathological phenotype, shock severity and clinical trajectory, along with the anticipated duration of support, anatomical variations and institutional factors are crucial determinants of MCS device use. Table 28.1 outlines the different MCS devices and their key features and effects.

Table 28.1



Characteristics of mechanical circulatory support devices

DEVICE	INTRA-AORTIC BALLOON PUMP	IMPELLA 2.5 / CP / 5 / 5.5 / RP	TANDEMHEART	EXTRACORPOREAL MEMBRANE OXYGENATION	EXTRACORPOREAL TEMPORARY VENTRICULAR ASSIST DEVICE	HEARTMATE III

Intra-Aortic Balloon Pump

Physiology Principles

IABP is one of the earliest types of MCS. It works on the principle of counterpulsation to increase mean arterial blood pressure, cardiac output, and coronary perfusion pressure. [19] It provides partial short-term mechanical support, with a multitude of factors influencing the absolute support; a modest 0.5–1.0 L/min increase in cardiac output can be provided under ideal circumstances. [20]

A flexible helium-filled balloon inflates in diastole and deflates in early systole and is timed to the cardiac cycle, either by electrocardiogram (ECG) or aortic pressure. Diastolic inflation of the balloon causes proximal displacement of the blood within the aorta, resulting in augmentation of coronary blood flow and increased myocardial oxygen supply. [21] Systolic deflation of the balloon reduces the LV afterload, lowering LV end-diastolic pressure (LVEDP), LV wall stress and subsequently myocardial oxygen demand. [19, 21, 22]

The IABP device is inserted percutaneously through a sheath in the femoral artery utilising a Seldinger technique. The inflatable balloon is positioned in the descending aorta. Optimal balloon position has the tip positioned 2–3 cm distal to the origin of the left subclavian artery and the proximal end of the balloon superior to the renal arteries. The tip has a radio-opaque marking to assist with optimal positioning. Positioning can be confirmed with guided fluoroscopy, transoesophageal echocardiography or chest x-ray.

Balloon positioning and timing influence the efficacy of the IABP, early inflation or late deflation can result in increased LV afterload and increased myocardial oxygen demand. ECG interference and cardiac arrhythmias are the most common causes of inaccurate timing.

Significant aortic regurgitation, aortic dissection, clinically significant aortic aneurysm and uncontrolled sepsis are absolute contraindications to IABP use. There are several relative contraindications which may increase the complications seen with its use, including an uncontrolled bleeding disorder, severe peripheral atherosclerotic disease, left ventricular outflow tract obstruction and cardiac arrhythmias.

Indications and Clinical Outcomes

Since its introduction in the late 1960s the IABP has been used widely in diverse clinical scenarios, including myocardial infarction, CS and during myocardial revascularisation in both interventional cardiology or cardiac surgery.[23] CS associated with acute myocardial infarction (AMI-CS) was the principal indication for IABP utilisation until the publication of the IABP-SHOCK II trial in 2012.[7,24] This large, randomised control trial demonstrated that patients with AMI-CS who underwent early revascularisation with optimal medical therapy did not have a significant short or long-term survival benefit from adjuvant IABP support.[25] IABP use in this population has substantially declined since and many international societies do not recommend its use in this setting.[7,26]

The CRISP-AMI trial demonstrated that the IABP use did not reduce infarct size in patients with anterior ST-elevation AMI (STEMI) without CS.[27] The elective use of IABP in high-risk percutaneous coronary intervention (PCI) has been evaluated and shown not to reduce the incidence of major adverse cardiac and cardiovascular events,[28] however, long-term data shows mortality benefit in patients with severe ischaemic cardiomyopathy undergoing PCI.[29,30]

Observational studies have shown the potential benefit of IABP in patients with mechanical complications following myocardial infarction including ventricular septal rupture and acute mitral regurgitation.[31,32]

The evidence available for the use of IABP in CS associated with acute decompensated heart failure (ADHF-CS) is limited to single-centre, non-randomised publications.[7] These studies have suggested that a subset of ADHF patients have improvements in CO and that IABP may serve as a bridge to long-term MCS.[33–36] A prospective, randomised, multicentre study (Altshock-2) is currently underway to assess the potential benefits of IABP in this patient population.[37]

There is low-level evidence to support the use of IABP in patients with angina unresponsive to medical treatment who do not have access to prompt PCI or coronary artery bypass graft surgery (CABG).[38–40] Intraoperative IABP use for weaning from cardiopulmonary bypass in CABG patients is common practice in some institutions. There is minimal evidence to support its use in this patient population; however, without MCS assistance, these patients are unlikely to separate from bypass. Its requirement is indicative of serious, often irreversible pathology, with associated high mortality and reports of up to 40% requiring a long-term MCS. [38]

Impella

Physiology Principles

The Impella device is a percutaneous microaxial flow pump that provides temporary circulatory support by ventricular unloading and augmentation of cardiac output. The microaxial flow pump is based on the principle of an Archimedes screw. Its functionality is dependent on ventricular preload and flow through the pump will decrease with increasing ventriculo-aortic pressure gradient. [7,41] It delivers blood from the LV into the aorta in a continuous, non-pulsatile manner, reducing ventricular size, end-diastolic pressure and wall tension, resulting in reduced ventricular work and myocardial oxygen consumption. [42–44] The overall increase in systemic perfusion pressure, combined with decreased LV wall tension has been shown to improve coronary blood flow. [45]

Impella is available in various models, which vary in size, insertion technique and maximal flow capacity. Flow ranges from 2.5 to 5.5 L/minute depending on the selected device. The smaller devices are inserted via the femoral artery via a 12-14 Fr introducer and advanced retrogradely to traverse the aortic valve. [43] The device is positioned under combined fluoroscopic and echocardiographic guidance, optimally into the middle of the LV, approximately 3.5 cm below the aortic valve. [19] The larger device sizes (Impella 5 and Impella 5.5) require a larger introducer and placement is usually via the axillary artery through a surgical incision. [19]

Post-insertion, the Impella device is connected to an external controller, allowing the level of support to be altered depending on the clinical scenario and patient progress. Set levels, designated P2-P9, vary the pump revolutions per minute (RPM) and delivered support.

The Impella RP is specifically designed for right heart support. It is inserted percutaneously through the femoral vein and is advanced to cross both the tricuspid and pulmonary valves. In this configuration the device drains the inferior vena cava (IVC) and delivers blood to the pulmonary artery, bypassing the right ventricle. [46]

Mechanical aortic valve and LV thrombus are absolute contraindications to the use of an Impella. Relative contraindications include severe aortic stenosis or regurgitation, small LV cavity, post-AMI ventricular septal defect, aortic aneurysm and severe peripheral vascular disease. [15, 41]

Indications and Clinical Outcomes

The use of Impella devices is increasing worldwide with a focus on providing temporary support for percutaneous cardiac procedures and CS. Clinical studies involving Impella have typically been non-randomised or very small patient samples and although physiologically promising its best impact is yet to be established.

Impella compared with IABP use in AMI-CS has been evaluated in two randomised studies (ISAR-SHOCK [47] and IMPRESS [48]), both studies had small patient samples and although there were early haemodynamic improvements, no mortality difference was detected. A meta-analysis, with a pooled patient number of 728, concluded no difference in 30-day mortality. [49] An increased rate of vascular access complications and major bleeding occurred in the Impella group versus the IABP group. [50] Recent meta-analyses have suggested that mortality in AMI-CS patients improved with Impella insertion prior to PCI [51–53] and the use of higher mechanical circulatory support, such as the Impella 5.0 and CP. [50]

Impella utilisation is increasing in patients undergoing high-risk coronary procedures (HR-PCI) with wide variation in practices and outcomes. [54] There is no standardised definition for HR-PCI, however common demographics include, advanced age, complex coronary artery disease, low ejection fraction and multi-morbid patients. In this clinical setting, transient coronary occlusion is required to complete the PCI and be associated with poor myocardial perfusion, haemodynamic instability and systemic hypoperfusion. [19, 55] The PROTECT II trial randomly assigned patients undergoing high-risk PCI to Impella or IABP, with a primary endpoint of composite adverse effects. It found no difference in the incidence of major adverse events but was terminated early due to futility. [56] There is conflicting evaluation of population database outcomes regarding survival and complication rates,[54],[57] concluding that further robust trials evaluating the Impella in this patient population are required.

Ventricular Assist Devices

Physiology Principles

Durable ventricular assist devices (VAD) facilitate long-term MCS in patients with heart failure. The HeartMate III is the only available adult device for new implantation at the time of writing, it provides continuous flow and assists the failing heart by increasing perfusion and offloading the ventricle. Device function is highly preload dependent and afterload sensitive, therefore a left-sided VAD (LVAD) requires a functioning RV to deliver adequate preload.[46]

The surgically implanted portion of a VAD consists of an inlet cannula, a centrifugal pump with a magnetically levitated impeller and a flexible outflow graft. For an LVAD, an LV apical core is excised to place the inlet cannula, with the outflow graft located into the ascending aorta. There is variable practice regarding the placement of the inlet cannula for a right VAD (RVAD); it may be placed into the right atrium or ventricle; the outflow graft is placed in the pulmonary artery. The VAD pump receives power from a tunnelled ‘driveline’ which is connected to an external controller and batteries.

Indications and Clinical Outcomes

Long-term MCS support with a VAD should be considered for selected patients with advanced heart failure symptoms (New York Heart Association class IIIB-IV), with reduced ejection fraction (HFrEF), who are dependent on intravenous inotropes or temporary MCS.[58] The 1- and 5-year survival post LVAD implantation has improved over the last decade, at 83.0% and 51.9% respectively.[59] The rate of adverse events such as stroke and gastrointestinal bleeding and hospital readmission has also reduced significantly over the last decade, with changes linked to technology improvements with the HeartMate III device.[59]

Durable VADs can be implanted as a bridge to cardiac transplant (BTT) or as permanent therapy, referred to as destination therapy (DT). [60] An additional subset of patients is referred to as a bridge to candidacy (BTC); these patients are not initially eligible for heart transplant listing at the time of durable VAD insertion, however, transplant is the ultimate intention. [61] There are a small number of patients in whom the heart recovers sufficiently for the VAD device to be explanted.

There is no isolated, gold-standard prognostic marker or risk score that identifies the optimal timing for VAD insertion. The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) classification system provides some risk stratification on patients who are likely to benefit from durable VAD implantation. Patients with an INTERMACS profile of 1–3 are likely to have survival benefit, profile 4 may benefit and profiles 5–7 are unlikely to benefit more than optimal medical management. [61], [62] Implantation in advanced age, high frailty, after the development of multi-organ dysfunction, fixed pulmonary vascular resistance or CS are known to worsen mortality. [63] Early involvement of an advanced heart failure cardiology team will facilitate early shared decision making. [61]

Extracorporeal Membrane Oxygenation

Physiology Principles

Veno-arterial extracorporeal membrane oxygenation (V-A ECMO) is a rapidly deployable, short-term system for complete or partial support of the circulatory system. Traditionally, veno-arterial (V-A) ECMO has been employed by surgical staff in operative settings, but progressively it is being applied outside of these settings. ECMO cannulae can be safely inserted using a percutaneous dilation technique or by an open surgical approach. Serial percutaneous dilation avoids making a skin incision and can achieve a seal between the skin and cannulae, reducing bleeding complications. It can be performed quickly, in a range of clinical spaces and scenarios without the need for surgical equipment or staffing.

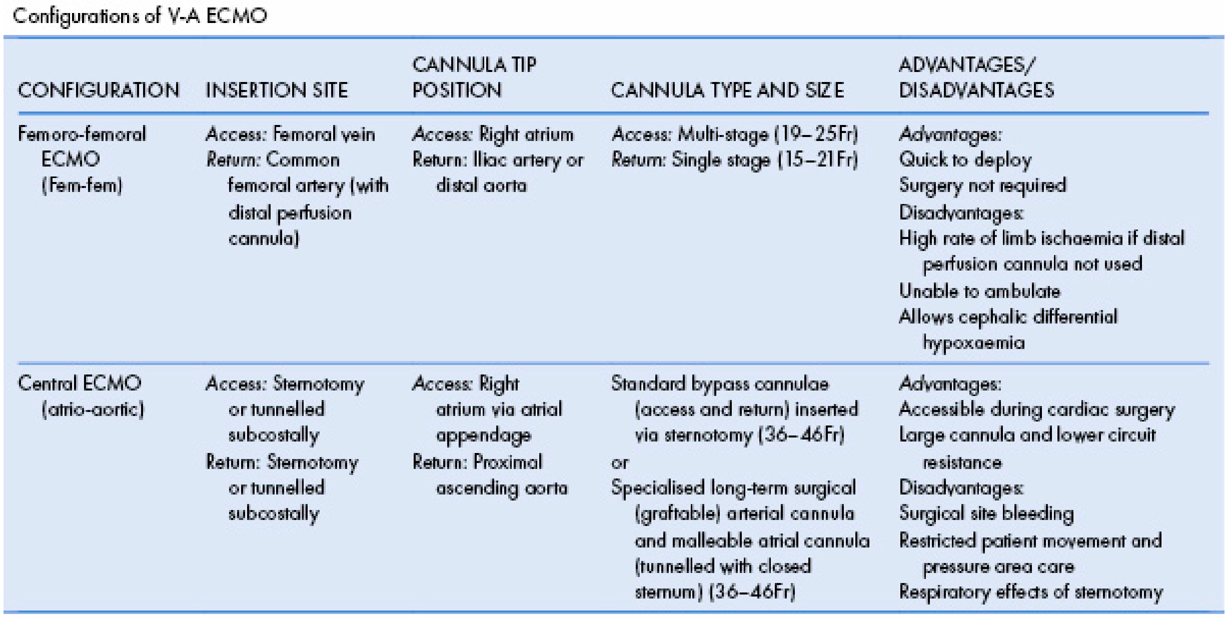
Mode

In peripheral V-A ECMO, blood is removed from the right atrium and adjacent veins and then returned retrograde to the aorta, bypassing the native heart and lungs. The V-A ECMO circuit comprises a specialised access cannula to drain venous blood, an external circuit (tubing), a gas exchange device (oxygenator) where blood becomes enriched with oxygen and has carbon dioxide removed, and a return cannula through which circuit blood returned to the arterial system. A centrifugal pump drives the circuit blood flow, up to the maximal flow of 5–7 L/min. Oxygen is delivered to the circuit via a connection of fresh gas flow to the oxygenator. Additional information regarding ECMO physiology and gas exchange principles can be found in the ECMO for respiratory support chapter (Chapter 50).

Configuration

The configuration of V-A ECMO determines the manner in which the ECMO circuit interacts with the native circulation, and configurations are defined by the site of cannulae insertion. In adults, cannulation can be peripheral or central, with a combination of access and return sites. Access is most commonly via the femoral vein, with the right internal jugular vein as an alternate site. Return is typically via the femoral artery, or infrequently via a graft to the right subclavian artery or main pulmonary trunk. The common configurations are outlined in Table 28.2 .

Table 28.2



Configurations of V-A ECMO

CONFIGURATION	INSERTION SITE	CANNULA TIP POSITION	CANNULA TYPE AND SIZE	ADVANTAGES/ DISADVANTAGES
Femoro-femoral ECMO (Fem-fem)	*Access:* Femoral vein *Return:* Common femoral artery (with distal perfusion cannula)	*Access:* Right atrium *Return:* Iliac artery or distal aorta	*Access:* Multi-stage (19–25Fr) *Return:* Single stage (15–21Fr)	*Advantages:* Quick to deploy Surgery not required Disadvantages: High rate of limb ischaemia if distal perfusion cannula not used Unable to ambulate Allows cephalic differential hypoxaemia
Central ECMO (atrio-aortic)	*Access:* Sternotomy or tunnelled subcostally *Return:* Sternotomy or tunnelled subcostally	*Access:* Right atrium via atrial appendage *Return:* Proximal ascending aorta	Standard bypass cannulae (access and return) inserted via sternotomy (36–46Fr) or Specialised long-term surgical (graftable) arterial cannula and malleable atrial cannula (tunnelled with closed sternum) (36–46Fr)	*Advantages:* Accessible during cardiac surgery Large cannula and lower circuit resistance Disadvantages: Surgical site bleeding Restricted patient movement and pressure area care Respiratory effects of sternotomy

ECMO , Extracorporeal membrane oxygenation; *Fr* , French.

Blood Flow Principles

In patients supported with V-A ECMO is it important to recognise that there are two circulations: the patients persisting native circulation and the V-A ECMO blood flow that bypasses the heart and lungs.

Native cardiac function can vary from absent to near-normal during different phases of V-A ECMO support, and when present patients will retain pulsatile pulmonary and aortic blood flow. Oxygen (O_2) and carbon dioxide (CO_2) gas tensions of the native cardiac output will reflect pulmonary gas exchange and during partial ECMO support will be predominately delivered to the coronary and cephalic circulations. Arterial pulse pressure and end-tidal CO_2 ($ETCO_2$) excretion can be used as surrogate markers of native cardiac output. As V-A ECMO blood is returned to the arterial system, not the right atrium as in V-V ECMO, CO_2 is only delivered to the pulmonary circulation via the native cardiac output, therefore a falling ETCO $_2$ may reflect worsening RV delivery of blood to the pulmonary circulation.

V-A ECMO circuit blood flow settings are primarily chosen to achieve adequate overall systemic perfusion. ECMO circuit flow in combination with the native cardiac output equates to total body blood flow. Complications are minimised by having partial ECMO support whilst maintaining some native cardiac output.

The distribution of the returning V-A ECMO circuit blood within the arterial system is dependent on a number of factors including, the V-A ECMO configuration, ECMO circuit blood flow and the native cardiac output. During complete V-A support, the ECMO circuit provides blood flow to all systemic perfusion and therefore the arterial gas tensions will be reflective of the gas exchange across the oxygenator. However, as the heart recovers and blood is ejected from the left ventricle the gas tension is determined by the V/Q in the lungs. Differential hypoxia is discussed further in the Management and Complications section.

In contrast to V-V ECMO, recirculation is not seen during V-A ECMO support.

Indications and Patient Selection

V-A ECMO support allows time for reversible cardiac failure to recover and can provide organ support before, during or after therapeutic cardiovascular procedures. In selected patients with advanced irreversible cardiac failure, V-A ECMO may be used as a bridge to longer-term devices or heart transplantation and facilitate shared decision making.[64]

Patient selection is key to good outcomes with V-A ECMO. The likelihood of a patient receiving benefit from the application of V-A ECMO for CS depends on age, diagnostic category/cause of heart failure, severity of shock prior to commencement and associated chronic organ failures. Diagnostic categories can be classified into ‘Favourable’,[14], [65–75] ‘High Risk’[76], [77] and ‘Unfavourable’, related to the treatability of the underlying condition (Box 28.1). Box 28.2 outlines the pathological conditions and their respective diagnostic categories. Aortic dissection, aortic regurgitation and severe mitral regurgitation prevent the successful application of V-A ECMO.

Box 28.1

V-A ECMO indications and diagnostic categories

AMI , Acute myocardial infarction; *AMI-CS* , acute myocardial infarction – cardiogenic shock; *VAD* , ventricular assist device; *VSD* , ventricular septal defect.

Box 28.2

MCS support based on pathological phenotype

BiVAD , Biventricular assist device; *LV* , left ventricle; *LVAD* , left ventricular assist device; *RV* , right ventricle; *RVAD* , right ventricular assist device; *V-A ECMO* , veno-atrial extracorporeal membrane oxygenation.

The reported survival rate for all patients supported with ECMO for cardiac failure is 45%.[78] Despite increasing use over the last 20 years, low total patient numbers with significant heterogeneity have resulted in literature remaining mixed on the benefit of ECMO support.

The first trials assessing the efficacy of V-A ECMO in adult CS populations have recently been published and have not demonstrated patient survival benefits.[79, 80] It is reasonable to conclude at this stage that the growth of V-A ECMO in unselected populations with CS should not expand further and that any potential benefit from the support is confined to highly selected patients.

Other MCS Devices

The following devices and configurations are used less frequently, in specialised circumstances, with significant variation in utilisation by region.

TandemHeart

TandemHeart is a percutaneously inserted centrifugal continuous flow device that pumps blood extracorporeally from the left atrium (LA) to the iliac arterial system, supplying retrograde arterial perfusion. The inflow cannula is placed trans-septally into the LA via the femoral vein. As blood is withdrawn directly from the LA, it results in LV unloading, with a reduction in LV volume and pressure. [46] Cannulation is done using fluoroscopy to ensure correct placement and requires skilled personnel with experience in trans-septal puncture.

Protek Duo

The Protek Duo is a specialised dual-lumen cannula that can provide oxygenation and right ventricle support. The cannula is inserted percutaneously via the internal jugular vein, with its proximal inflow lumen positioned in the right atrium, and the distal outflow lumen in the main pulmonary artery. The cannula is connected to an extracorporeal circuit. A circuit without an oxygenator will provide isolated right heart support, whilst introducing an oxygenator will allow respiratory and right heart support. This technique was adopted by select centres during the COVID-19 pandemic for the treatment of ARDS. [81]

Combination Support

The use of ECMO in combination with an additional circulatory support device, such as IABP or Impella, to mitigate the ECMO-related side effects associated with LV distention has gained wide interest. [82], [83] IABP is the most frequently used adjunct, however, there is no randomised data to support the practice and available observational data is conflicting. [84] The combination of Impella and ECMO (ECPELLA or ECMELLA) provides greater LV unloading than IABP. As with IABP, no randomised data exists to support Impella use for LV unloading. There is an emerging body of observational data to suggest lower mortality with ECPELLA compared to

V-A ECMO alone; however, the practice is associated with increased rates of severe bleeding and haemolysis.[85]

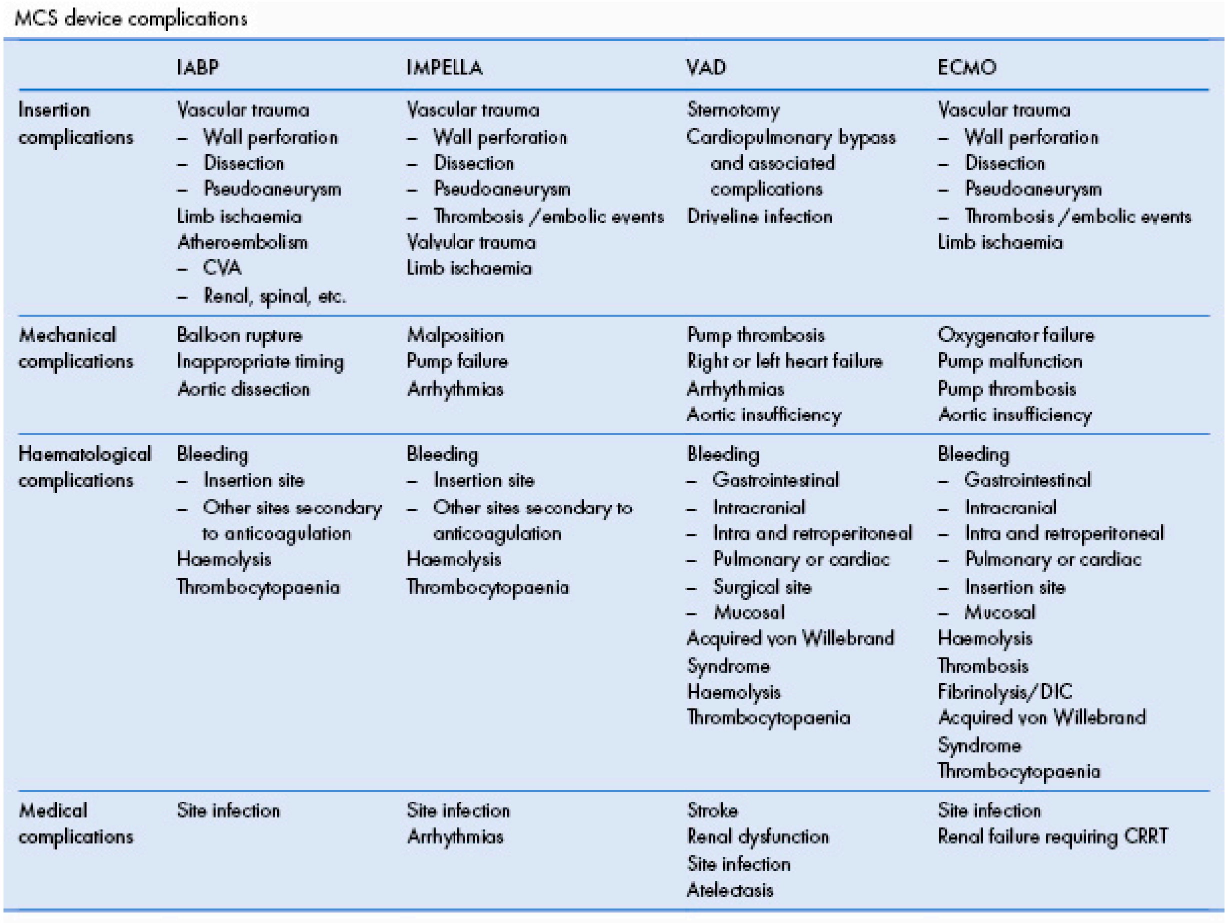
Extracorporeal Temporary Ventricular Assist Devices

Temporary ventricular assist devices (VAD) utilise similar cannulae, circuit tubing and pumps to ECMO, but do not include an oxygenator. They are configured to provide single ventricular mechanical support. A left VAD is configured using a left heart access cannula with an aortic return cannula, whilst a right LVAD is configured using right heart access with a pulmonary artery return. Biventricular VAD support configurations utilise both of the above configurations. Temporary VAD have a role in buying time to bridge patient selection for longer-term VAD or transplantation.

Mechanical Cardiac Support Device Management and Complications

The most common complication related to mechanical cardiac support is bleeding, and it is an independent predictor of mortality. Other complications related to MCS devices are listed in Table 28.3.[12,42,53,86–88]

Table 28.3



MCS device complications

	IABP	IMPELLA	VAD	ECMO
Insertion complications	Vascular trauma – Wall perforation – Dissection – Pseudoaneurysm Limb ischaemia Atheroembolism – CVA – Renal, spinal, etc.	Vascular trauma – Wall perforation – Dissection – Pseudoaneurysm – Thrombosis /embolic events Valvular trauma Limb ischaemia	Sternotomy Cardiopulmonary bypass and associated complications Driveline infection	Vascular trauma – Wall perforation – Dissection – Pseudoaneurysm – Thrombosis /embolic events Limb ischaemia
Mechanical complications	Balloon rupture Inappropriate timing Aortic dissection	Malposition Pump failure Arrhythmias	Pump thrombosis Right or left heart failure Arrhythmias Aortic insufficiency	Oxygenator failure Pump malfunction Pump thrombosis Aortic insufficiency
Haematological complications	Bleeding – Insertion site – Other sites secondary to anticoagulation Haemolysis Thrombocytopaenia	Bleeding – Insertion site – Other sites secondary to anticoagulation Haemolysis Thrombocytopaenia	Bleeding – Gastrointestinal – Intracranial – Intra and retroperitoneal – Pulmonary or cardiac – Surgical site – Mucosal Acquired von Willebrand Syndrome Haemolysis Thrombocytopaenia	Bleeding – Gastrointestinal – Intracranial – Intra and retroperitoneal – Pulmonary or cardiac – Insertion site – Mucosal Haemolysis Thrombosis Fibrinolysis/DIC Acquired von Willebrand Syndrome Thrombocytopaenia
Medical complications	Site infection	Site infection Arrhythmias	Stroke Renal dysfunction Site infection Atelectasis	Site infection Renal failure requiring CRRT

CRRT , Continuous renal replacement therapy; *CVA* , cerebral vascular accident; *DIC* , disseminated intravascular coagulation.

Anticoagulation, Bleeding and Thrombosis

The spectrum of MCS device size, mechanics, and duration of use results in a wide variation of antithrombotic requirements. Thrombus can form within the heart chambers, around valves or be associated with device cannulae, circuits or pumps; routine anticoagulation should be utilised for most devices. Unfractionated Heparin remains the first-line therapy in most centres; however, there is significant practice variation and definitive recommendations are lacking. Targets used included activated partial thromboplastin time (APTT), activated clotting time (ACT), anti-factor Xa assay (Anti-Xa) and thromboelastogram (TEG); no test has proven benefit over another.

MCS-related bleeding is multifactorial; related to anticoagulation and antiplatelet requirements, thrombocytopaenia, acquired coagulation deficits and haemolysis. [19] The rates of major bleeding increase with the invasiveness of the device. [89]

Distal Limb Ischaemia

Distal limb ischaemia caused by MCS devices is associated with increased mortality. Large arterial cannula size and small femoral artery size are key risk factors. All patients with a peripheral ECMO arterial return catheter should have a distal perfusion cannula inserted to prevent limb ischaemia from occurring as a result of the occlusive and compressive effects of the return cannula. [90] IABP and Impella use smaller catheter sizes than ECMO and can often be placed without distal limb ischaemia, however, patients with small femoral arteries may still be at risk. [91]

Differential Hypoxia

A significant lung shunt associated with an improving native cardiac output can result in large degrees of differential oxygenation in patients supported with peripheral V-A ECMO. It occurs when hypoxaemic blood from the pulmonary circulation is ejected from the left heart whilst fully oxygenated blood enters the arterial circulation from the ECMO circuit. In configurations with a femoral arterial return cannula, highly oxygenated ECMO circuit blood is preferentially distributed to the caudal regions as native cardiac function improves, whilst deoxygenated blood leaving the left ventricle predominantly perfuses the coronary and cephalic circulations. Monitoring arterial oxygen saturation and tension via the right upper limb can allow early detection of the proportion of deoxygenated native cardiac output reaching the coronary and cephalic circulations.

Management includes weaning off any inotropic agents, treating the lung shunt with positive-pressure ventilation, PEEP, bronchoscopy, and inhaled nitric oxide if necessary. Increasing the ECMO circuit blood flow can reduce the proportion of venous return able to reach the lungs. If severe hypoxaemia persists despite the above measures, consideration of changing the mode of ECMO support from V-A to V-V, or V-AV should be considered.

Loss of Pulsatility and LV Distention Syndrome

The ability of the heart to open the aortic and pulmonary valves and contribute to cardiac output may be lost in patients on V-A ECMO. Loss of pulsatility may be related to progressive cardiac failure from the underlying disease process or result from extrinsic cardiac compression. Extrinsic cardiac compression from bleeding is more common in the postoperative cardiac setting and should be managed surgically.

Severe myocardial failure with loss of pulsatility and failure of aortic valve opening can result in two major complications, intracardiac thrombus and LV distention syndrome. Management in this scenario is aimed at the preservation of some intracardiac blood flow and higher anticoagulation targets. Increased inotropic support, reduction in arterial pressure and reduced ECMO circuit blood flow may improve cardiac blood flow.

LV distention syndrome can occur in pathology that results in a predominance of left ventricular heart failure compared with RV failure, the presence of aortic or mitral valve regurgitation or high mean arterial pressure. These pathologies can result in progressive distension of the left ventricle and congestion of the pulmonary circulation and lungs.

Non-invasive management options include positive-pressure ventilation and high PEEP, reduction in mean arterial pressure and in some instances decreasing inotropic support (inotropes may increase RV function more than LV function). Invasive options include percutaneous insertion of IABP or Impella, or surgical manoeuvres such as atrial septostomy or implantation of a left heart drainage cannula. [92] The populations in which LV decompression or ‘venting’ offers benefit remains unclear and this is a topic undergoing significant evolution.

Weaning from MCS

Suitability to wean from support reflects an improved clinical status and does not require full restoration of underlying cardiac function. A weaning trial is an intentional decrease in the level of support that allows the evaluation of native heart function. IABP weaning involves the reduction of either the augmentation ratio or balloon inflation volume. Impella device support can be sequentially weaned by reducing the P-level (P9-P2), the optimal timing rate of these reductions is unclear and should be tailored to particular clinical scenarios.[93]

In V-A ECMO an echocardiographic weaning study is required to assess suitability for decannulation.[94] During a weaning study, haemodynamics, ventricular function and native cardiac output are monitored and measured at progressively lower ECMO circuit blood flow rates.[95]

Extracorporeal Cardiopulmonary Resuscitation

Extracorporeal cardiopulmonary resuscitation (ECPR) is the commencement of V-A ECMO in patients where conventional cardiopulmonary resuscitation (CCPR) has been unable to achieve sustained return of spontaneous circulation (ROSC). Favourable neurological outcome following CA diminishes rapidly with prolonged conventional CPR without ROSC due to cerebral hypoperfusion. V-A ECMO restores a perfusing circulation in the absence of native cardiac function allowing more time for reversible causes of the arrest to be diagnosed and treated.

ECPR is a time-critical, complex intervention that requires significant training and robust patient selection. Reported survival rates range from 8% to 43%, with younger age, witnessed arrest, immediate CPR and ventricular fibrillation or tachycardia rhythm affording high survival.[96–98]

There is increasing interest in ECPR, with three recently published randomised trials (ARREST trial, Prague OHCA study and INCEPTION trial) comparing an ECPR strategy for out-of-hospital cardiac arrest (OHCA) to local standard care.[97], [99], [100] The evidence presented in these trials is conflicting; the ARREST and Prague OHCA trials suggested an increase in survival with good neurological outcomes, whilst the INCEPTION trial failed to demonstrate benefit for ECPR. The divergent results of these studies illustrate the complexity of implementing ECPR programmes; and that the beneficial results obtained in one centre may not be replicated in another due to training, logistical and geographical challenges.

Acute coronary syndromes, investigations and interventions

Shanthosh Sivapathan, Faraz Pathan and Ian Seppelt

Introduction

Cardiovascular disease (CVD) is the leading cause of death in Western industrialised society, with coronary artery disease (CAD) being responsible for about 40% of these.[1] Up to 70% of CAD deaths occur outside hospital as ‘sudden death’ from cardiac arrest.[2] In persons over age 40, acute myocardial infarction (MI) is the cause of approximately 20% of all deaths. Of those who die acutely, 50%–65% have no previous history of cardiac disease. Of patients admitted to hospital, early mortality is 5%–7% (much higher in at-risk groups) and may rise to 7%–18% by 12 months.[3–6] Improving in-hospital and longer-term CAD mortality requires rapid identification of at-risk patients and the implementation of evidence-based treatments.

Myocardial Infarction

Myocardial infarction (MI) is present when there is evidence of myocardial necrosis in a clinical setting consistent with myocardial ischaemia. Diagnosis involves clinical suspicion, with supportive electrocardiography (ECG), biomarkers, echocardiography or autopsy findings confirming the diagnosis.

MI can result from different pathological and epidemiological mechanisms (Box 29.1).[2,7,8] Each mechanism may have a different prognosis despite similar biomarker or ECG changes and the patterns of MI may be different in an emergency department, surgery or intensive care unit (ICU) population. This may be clinically important when applying trial results or guidelines to such populations. Small amounts of myocardial necrosis can occur with heart failure (HF), arrhythmias, pulmonary embolism or after uneventful cardiac procedures; these are better labelled ‘myocardial injury’ rather than MI. [7]

Box 29.1

Universal classification of myocardial infarction

Type 1: Spontaneous myocardial infarction

Spontaneous myocardial infarction related to ischaemia due to a primary coronary event such as plaque erosion and/or rupture, fissuring or dissection. The patient may have severe coronary artery disease (CAD) but on occasion non-obstructive or no CAD.

Type 2: Myocardial infarction secondary to an ischaemic imbalance

This occurs in instances of myocardial injury with necrosis where a condition other than CAD contributes to an imbalance between myocardial oxygen supply and/or demand; for example coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachy-/brady-arrhythmias, anaemia, respiratory failure, hypotension and hypertension with or without left ventricular hypertrophy (LVH).

Type 3: Myocardial infarction resulting in death when biomarker values are unavailable

Cardiac death with symptoms suggestive of myocardial ischaemia, and presumed new ischaemic changes or new LBBB, but death occurring before blood samples could be obtained, before cardiac biomarkers could rise or, in rare cases, biomarkers were not collected.

Type 4a: Myocardial infarction related to percutaneous coronary intervention

Significant cardiac biomarkers rise from normal or by more than 20% if previously elevated. In addition, either:

i. symptoms of myocardial ischaemia, *or*
ii. new ischaemic ECG changes or LBBB, *or*
iii. angiographic loss of patency or persistent flow abnormalities, or embolisation, *or*
iv. imaging demonstration of loss of viable myocardium or regional wall motion abnormality.

Type 4b: Myocardial infarction related to stent thrombosis

Myocardial infarction associated with stent thrombosis detected by coronary angiography or autopsy in setting of myocardial ischaemia and with a significant rise and/or fall of biomarkers.

Type 5: Myocardial infarction related to coronary artery bypass grafting (CABG)

Myocardial infarction associated with CABG arbitrarily defined by elevation of cardiac biomarker values from normal baseline to above 10 times the URL. In addition, either:

i. new pathological Q-waves or LBBB, *or*
ii. angiographic documented new graft or new native coronary artery occlusion, *or*
iii. imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Acute Coronary Syndromes

Acute coronary syndromes (ACS) describe the spectrum of patients who present with chest discomfort or other symptoms of acute myocardial ischaemia (Box 29.2). ACS can be further divided into ST-elevation myocardial infarction (STEMI) and non–ST-segment elevation myocardial infarction (NSTEMI), including unstable angina (UA), which reflects myocardial ischaemia without cell injury. [4] Both are invariably caused by recent thrombus formation on pre-existing coronary artery plaque, occasionally by embolism or artery dissection. In this sense, they differ from stable angina, which is usually precipitated by increased myocardial oxygen demand with significant background coronary artery narrowing. ACSs are medical emergencies and are one of the most frequent causes of hospital and coronary care unit admission.

Box 29.2

Classification of acute coronary syndromes

Acute coronary syndrome (ACS)

A spectrum of clinical conditions characterised by acute chest pain or myocardial ischaemia. Pain is of recent origin or is more frequent, severe or prolonged than known angina, is more difficult to control with medication or occurs at rest or with minimal exertion.

ACS includes myocardial infarction with ST-segment elevation (STEMI), myocardial infarction in the absence of ST-segment elevation (NSTEMI) and unstable angina. An initial clinical subdivision of ACS is made on the presence or absence of electrocardiography ST-segment elevation.

STEMI

Patients presenting with ST-segment elevation ACS will invariably display initial or subsequent troponin elevation, although the extent of myocardial infarction and complications may be significantly moderated by intervention.

NSTEACS

Patients who present without ST-segment elevation may later (after testing of biomarkers) be determined to have:

i. *NSTEMI:* cardiac biomarkers elevated indicating myocardial infarction
ii. *Unstable angina:* no evidence of cardiac biomarker elevation.

An immediate clinical imperative is identification of patients with ST-segment elevation (STE), as rapid reperfusion therapy is strongly indicated in this group.

Aetiology and Risk Factors

Atheroma deposits in coronary artery walls provide the substrate for ACS. Risk factors for CVD and CAD include cigarette smoking, diabetes, dyslipidaemia, hypertension and family history. [9] Strategies targeting standard modifiable risk factors (SMuRFs) such as diabetes, hypercholesterolaemia, hypertension and smoking have had significant improvement in prevention and treatment. [10] About 85% of patients presenting with an initial MI have at least one risk factor. [11] However, an increasing proportion of patients with MI are presenting with none of the SMuRFs. [12], [13] SMuRF-less patients is a term used to describe patients presenting with ACSs with no known modifiable risk factors. Examples of non-modifiable risk factors would include family history, ethnicity or autoimmune conditions such as systemic lupus erythematous or rheumatoid arthritis. [14], [15] SMuRF-less patients (particularly women) presenting with STEMIs have higher 30-day mortality compared to patients who have at least one traditional risk factor. [10]

Cessation of smoking, lowering plasma cholesterol (diet and medications), weight loss and adoption of an active lifestyle can all help reduce the development of CAD. [9], [16] In a large meta-analysis of trials comparing antihypertensive regimens in patients at high risk of CVD, a 10 mm Hg reduction in systolic blood pressure (SBP) resulted in a relative risk reduction (RRR) in major CVD events (20%), coronary heart disease

(17%), stroke (27%) and HF (28%) with a 13% RRR in all-cause mortality.[17]

Pathophysiology[17, 18]

Formation of thrombus upon ruptured, fissured or eroded atheromatous plaque is the usual precipitant of an ACS (Fig. 29.1).[7, 9, 19] Atherosclerotic plaque formation is probably initiated by vessel wall injury that may commence as early as childhood. 'Fatty streaks' formed from lipid engorged macrophages (foam cells), and T lymphocytes, accumulate in the intima of arteries. Such cells accumulate lipids but are also pro-inflammatory. As large amounts of lipids accumulate they may become covered by a fibromuscular cap forming a 'fibrous plaque'. Plaque development is often slow but may rapidly accelerate in people with risk factors.

'White thrombus'
Vessel occlusion

B

The two-part diagram contains labelled parts, A and B, each presenting a cross-section of a blood vessel with sequential thrombus development. In part A, the inner vessel wall features a ruptured plaque with a central lipid core and a labelled endothelium. Arrows mark the direction of blood flow from left to right. A dense accumulation of platelets is attached at the rupture site, forming an initial thrombus. Several smaller fragments, labelled as distal platelet emboli, are shown downstream within the lumen. In part B, the same vessel section exhibits a larger thrombus composed of fibrin and red blood cells above the platelet aggregation. This mass partially blocks the lumen, marked as vessel occlusion. The upstream platelet deposit remains visible beneath the added layer. Both parts illustrate the progression from early platelet accumulation to a more advanced obstructive thrombus composed of cellular and fibrin components.

FIG. 29.1 (a) Plaque rupture exposes thrombogenic lipids. 'White thrombus' is formed by adherent activated platelets. Coronary artery narrowing, distal platelet embolisation or arterial spasm can cause ischaemic myocardial pain and possible myocardial necrosis. This lesion is unstable and may lead to thrombin activation. 'White thrombus' is not removed by thrombolytic therapy. (b) Thrombin activation leads to a mesh of fibrin and red blood cells (RBCs) or 'red thrombus'. Arterial occlusion may result and, in arteries without adequate collateral circulation, myocardial necrosis follows. Complete arterial occlusion is suggested by ST-segment elevation on the electrocardiogram. Prompt reperfusion with thrombolytic therapy or with invasive coronary procedures may prevent extensive myocardial necrosis.

'Vulnerable plaque' is often rich in lipids and covered by a thin fibrin cap. Fatal MI may demonstrate plaque **rupture (75%)** or plaque **erosion (25% of cases)** . Ruptured plaque may have a thin cap, large necrotic core, inflamed and neovascularised tissue and haemorrhage. Eroded plaque is often thin walled with a core that has less necrosis and inflammation. Both expose thrombogenic lipids and collagen, which are potent activators of platelets.

Platelet adherence and activation, and subsequent activation of the clotting cascade, resulting in 'atherothrombotic processes'. Platelets aggregate to form *'white thrombus'* . The final common pathway of thrombus formation is via activation of the platelet glycoprotein (GP) IIb/IIIa receptor, which binds fibrinogen and cross-links platelets. Activation of coagulation pathways by exposed lipid and fibrin, and by activated platelets, leads to thrombin activation and fibrin clot formation. Red cells are enmeshed in this so-called *'red thrombus'* complex, which surrounds the 'white thrombus'. Whilst *'culprit lesions'* of STEMI can be small (<50% stenosis), studies suggest that 86% of patients had at least moderate stenosis (>50%) and 67% had severe stenosis (>70%).[20, 21]

The pathophysiology above has immediate relevance to treatment (see Fig. 29.1).

When discussing the pathophysiology of ACS, it is important to mention the impact of COVID-19 infection on our understanding of this condition. COVID-19 predominantly affects the lungs resulting in diffuse alveolar injury and immunothrombosis in the pulmonary capillary networks.[22] The pathogenesis and consequences of ACS in COVID-19 infections are not well understood. The assumption is that patients with COVID-19 infections develop both type 1 myocardial infarction (MI) secondary to acute plaque rupture and type 2 myocardial infarction as a result of supply–demand mismatch.[23] In addition to this a subset of patients suffered from myocardial infarctions without obstructive coronary arteries (MINOCA), which will be discussed in greater detail later in this chapter.[22] These patients should be managed according to standard guidelines. The difficulty resides in managing a subset of patients who develop ACS in the context of COVID-19 infection and develop immune vasculitis and hypercoagulability.[24] Moreover, although uncommon, other complications such as myocarditis and pericarditis have also been thoroughly characterised following COVID-19 infection.[24]

- **Antiplatelet agents** prevent platelet adherence, limiting and even reversing ‘white thrombus’ formation. Aspirin blocks thromboxane A_2 synthesis but fails to block platelet activation by thrombin, adenosine diphosphate (ADP) and collagen. New agents may target ADP receptors (e.g. clopidogrel and prasugrel) or may inhibit cyclo-oxygenase (e.g. aspirin).
- **Thrombolytic agents** lyse ‘red thrombus’ but not ‘white thrombus’.
- **Antithrombin agents** (e.g. heparins) limit thrombin activation. Current fibrin-specific thrombolytic agents lyse fibrin and red cell thrombus but paradoxically may increase surface thrombin activation.

Totally occluding thrombus causes myocardial necrosis unless there is collateral flow or rapid thrombus clearance. Occlusion is often accompanied by ECG changes of STE although this is not absolute. Non-occlusive thrombus may be asymptomatic or may cause USA or MI, especially if spasm or distal thrombus embolisation occurs. Thrombus retrieved ‘early’ during percutaneous coronary intervention (PCI) thrombectomy in STEMI patients surprisingly may be predominantly ‘white thrombus’ (up to 30% of samples), with smaller infarction. Red thrombus may be a sign of a maturing clot.

Infarct size determines

- left ventricular (LV) systolic function impairment
- stroke volume decrease
- ventricular filling pressure rise (leading to pulmonary congestion and hypotension that may impair coronary perfusion pressures and exacerbate the myocardial ischaemia)
- LV diastolic dysfunction.

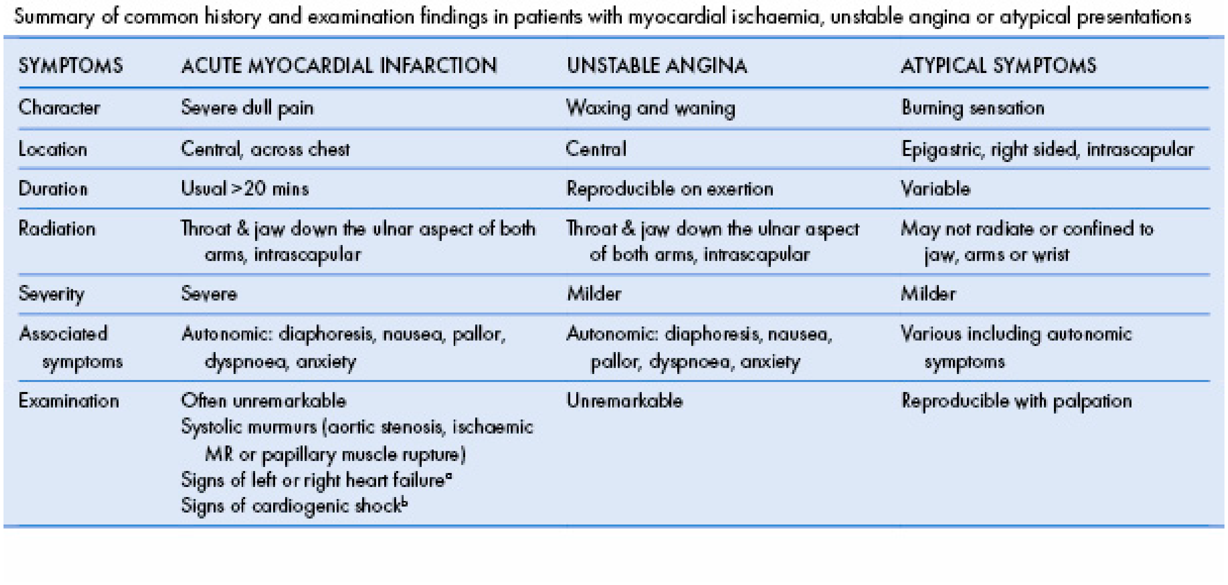
Clinical Presentation

The diagnosis of myocardial ischaemia is usually made (suspected) on the basis of clinical history and ECG.[2,5–8,25]

History [26]

Patients with myocardial ischaemia can present with chest pain or pressure, syncope, palpitations, dyspnoea, fatigue or sudden death. Prodromal UA symptoms may occur in the days preceding infarction in 20%–60% of patients, although this is less likely in young patients. Table 29.1 is a summary of the common history and examination findings for patients presenting with myocardial ischaemia, UA and atypical chest pain.[2,5,6,26,27]

Table 29.1



Summary of common history and examination findings in patients with myocardial ischaemia, unstable angina or atypical presentations

SYMPTOMS	ACUTE MYOCARDIAL INFARCTION	UNSTABLE ANGINA	ATYPICAL SYMPTOMS
Character	Severe dull pain	Waxing and waning	Burning sensation
Location	Central, across chest	Central	Epigastric, right sided, intrascapular
Duration	Usual >20 mins	Reproducible on exertion	Variable
Radiation	Throat & jaw down the ulnar aspect of both arms, intrascapular	Throat & jaw down the ulnar aspect of both arms, intrascapular	May not radiate or confined to jaw, arms or wrist
Severity	Severe	Milder	Milder
Associated symptoms	Autonomic: diaphoresis, nausea, pallor, dyspnoea, anxiety	Autonomic: diaphoresis, nausea, pallor, dyspnoea, anxiety	Various including autonomic symptoms
Examination	Often unremarkable Systolic murmurs (aortic stenosis, ischaemic MR or papillary muscle rupture) Signs of left or right heart failure[a] Signs of cardiogenic shock[b]	Unremarkable	Reproducible with palpation

[a] Signs of left heart failure such as gallop rhythm, tachycardia, tachypnoea and basal crackle. Signs of right heart failure include hypotension, elevated jugular venous pressure with clear lungs.

[b] Poor peripheral perfusion, hypotension, oliguria and other features of 'low cardiac output'.

Differential diagnosis may include pericarditis, aortic dissection or massive pulmonary embolism.

Atypical or silent presentations are common (25% of STEMI patients and 45% of non–ST-elevation myocardial infarction [NSTEMI]).[8, 25, 28] Patients who present without classic chest discomfort are less likely to receive definitive treatment. Such presentations are more common in patients who are elderly, female, diabetic, obese or have a history of HF.

The assessment of clinical symptoms alone is insufficient for risk stratification and the severity of pain does not usually correlate with the extent of infarction.

Conditions that can mimic ACS but do not benefit from thrombolysis include critical illness, pericarditis and Takotsubo syndrome.[4, 5, 29] Aortic dissection may be present in 1.3% of STEMI, and diagnosis may be realised during PCI.[30] If suspected on presentation, immediate echocardiography (and possible computed tomography angiography) is indicated to confirm the diagnosis and assist with surgical planning. Coronary artery involvement may cause associated MI.

Investigations

The presence of MI should also be qualified by:

- anatomical location and size
- causation (e.g. MI Type 1–5) (see Box 29.1)
- time from occurrence (acute, early and late).

Technological advances in biomarker assays allow the detection of very small infarcts.

Electrocardiography [31–35]

The ECG is the initial single most cost-effective, clinically useful and predictive test for diagnosis and guidance of the emergency treatment of MI. All patients presenting with symptoms suggestive of MI should have an ECG performed and interpreted by an experienced person within 10 minutes of arrival. [36] Initial ECGs may (i) reveal a significant ST-elevation acute coronary syndrome (STEACS); or (ii) suggest a non–ST-elevation acute coronary syndrome (NSTEACS). Serial 12-lead ECGs are necessary as STE may develop after initial assessment and changes may indicate response to therapies.

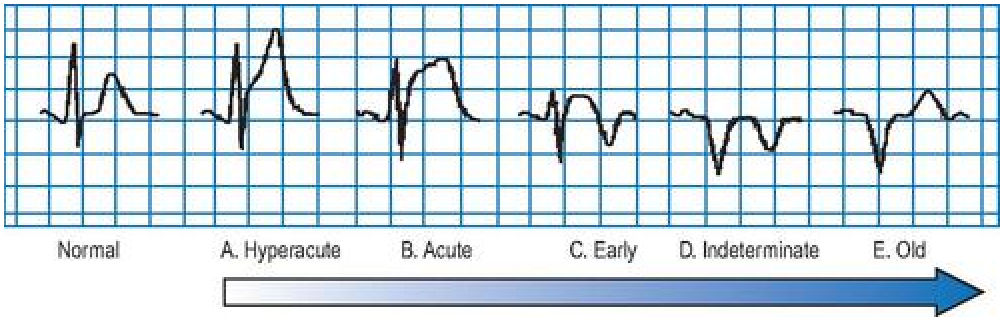
Acute and complete occlusion of a coronary artery usually leads to serial ECG changes in leads subtending the area of ischaemia, where the:

- number of leads involved broadly reflects the extent of myocardium involved
- height of initial STE is only modestly correlated with the degree of ischaemia [35]
- acute resolution of STE correlates well with reperfusion.

Recognition of STE and its evolution indicates patients in whom reperfusion therapy may interrupt, or minimise myocardial necrosis (Fig.

29.2). These changes are not stereotyped and may vary significantly but include:

- *hyperacute* (0–20 minutes): tall, peaking T-waves and progressive upward coving and elevation of ST-segments
- *acute* (minutes to hours): persisting STE, gradual loss of R-wave in the infarcted area. Progressive inversion of T-waves
- *early* (hours to days): loss of R-wave and development of pathological Q-waves in the area of ischaemia. Return or fall of ST-segments to baseline. Persistence of T-wave inversion
- *indeterminate* (days to weeks): pathological Q-waves with persisting T-wave inversion. ST-segments normalise (unless there is aneurysm)
- *old* (weeks to months): persisting deep Q-waves with normalised ST-segments and T-waves.



The sequential electrocardiographic tracing shows six segments aligned horizontally on a grid. Each segment shows a different stage of waveform progression labelled below as normal, A hyperacute, B acute, C early, D indeterminate, and E old. The first waveform, marked normal, shows a typical P wave, Q R S complex, and T wave. The hyperacute stage displays a tall, broad T wave. The acute stage presents an elevated S T segment with a broad Q R S complex. In the early stage, the S T segment is still elevated, but the waveform appears widened and distorted. The indeterminate stage shows evolving changes with deeper Q waves and inverted T waves. The final stage, marked old, shows persistent deep Q waves and a flattened or inverted T wave. Below the waveforms, a horizontal arrow fades gradually from left to right.

FIG. 29.2 Total acute coronary occlusion leads to serial electrocardiogram changes. The evolution is variable and may be interrupted or altered by successful reperfusion. ST-segment elevation is an early and relatively specific indicator of the need for acute reperfusion in patients with acute coronary syndrome.

Clinical skill is needed to identify those ECG changes that are probably due to MI (true positive but also false negative). Other causes of STE and T-wave changes that should *not* lead to thrombolytic therapy are shown in Box 29.3 .[7, 37, 38]

Box 29.3

Electrocardiogram patterns mimicking ST-segment elevation myocardial infarction

Normal variant (non-ischaemic STE mainly V2–V3)
Early repolarisation (notched J-point mainly in anterolateral leads)
Metabolic disturbance (mainly hyperkalaemia and hypercalcaemia)
Drug toxicity
Brugada syndrome
Pre-excitation (Wolff–Parkinson–White syndrome)
Pericarditis
Myocarditis
Previous (old) myocardial infarction
Left ventricular aneurysm
Spontaneously reperfused myocardium
Apical ballooning syndrome (Takotsubo or ‘broken heart’) has multiple causes, for example severe emotion and physical stress

Data from Thygesen K, Alpert JS, Jaffe AS, et al. Fourth universal definition of myocardial infarction (2018). *J Am Coll Cardiol* . 2018;72(18):2231–2264; and Pollak P, Brady W. Electrocardiographic patterns mimicking ST-segment elevation myocardial infarction. *Cardiol Clin* . 2012;30(4):601–615.

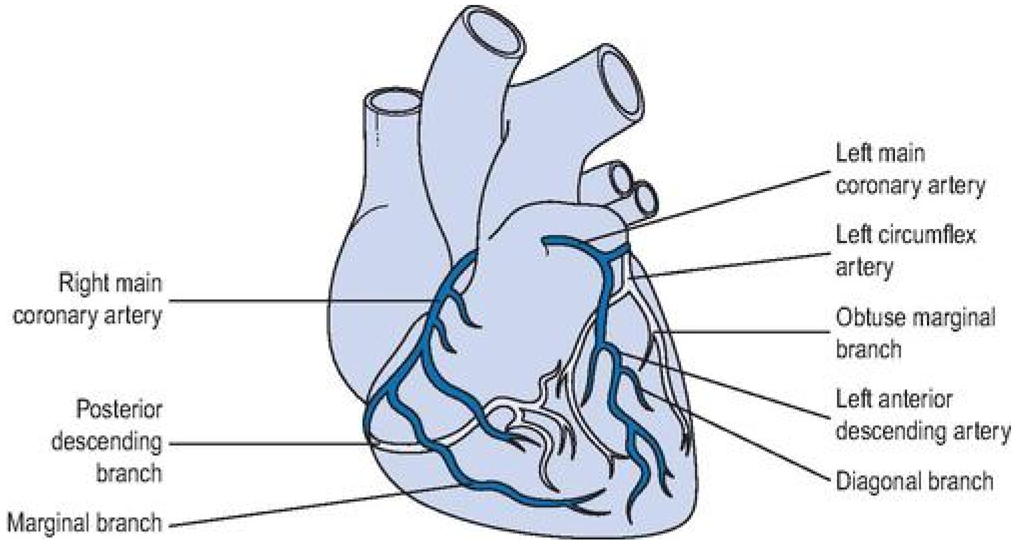
Takotsubo syndrome [39, 40] may mimic an ACS and can represent up to 1%–2% of STEACS-like presentations.

Patients with ACS but with ‘non-significant STE’ (NSTEACS until further subdivided by biomarker studies) are also at risk of MI and death. They commonly have active, non-occluding thrombus, or occlusion if present may be to an area with the collateral flow or with poor detection by standard lead placements. ECGs in these ACS patients may be normal or display [31–35] :

- ST-segment depression
- STE (insufficient to meet thrombolysis criteria)
- T-wave inversion or ‘normalisation’ of previous inverted T-waves.

Localisation of Infarction [31–35, 41] (Fig. 29.3)

Coronary artery anatomy is displayed in Fig. 29.3 . A very general relationship of ECG, MI locating leads and likely ‘culprit arteries’, is outlined in Table 29.2 and in cited references. [31–35] ECG ‘localisation’ may differ from angiography, echocardiography and autopsy findings, however, especially where there is collateral circulation or previous coronary artery bypass grafting (CABG). Approximately 40%–50% of patients may present with anterior infarctions which may be septal, anterior or lateral (Fig. 29.4A). [32] About 50% may present with acute inferior MI (see Fig. 29.4B), [31–35] which may involve an extension to the lateral, posterior or right ventricle (RV) myocardium.



Left main coronary artery
Left circumflex artery
Right main coronary artery
Obtuse marginal branch
Posterior descending branch
Left anterior descending artery
Diagonal branch
Marginal branch

The anatomical diagram of the heart with labels pointing to major coronary arteries and their branches. The right side of the heart includes labels for the right main coronary artery, the marginal branch, and the posterior descending branch. The left side includes the left main coronary artery, which bifurcates into the left circumflex artery and the left anterior descending artery. Additional branches from the left system are also labelled, including the obtuse marginal branch and the diagonal branch. All arteries and branches are illustrated as dark vessels running across the surface of the heart, following the contours of the myocardium.

FIG. 29.3 Coronary artery anatomy. The left anterior descending artery supplies the anterior two-thirds of the interventricular septum (septal perforators), anterior and lateral wall of the left ventricle (diagonal branches) and sometimes part of the right ventricle (RV). Circumflex (Cx) supplies the LV lateral (anterolateral marginal branches) and posterior walls, and occasionally its inferior aspect (posterior LV arteries: 15% of patients) and the posterior septum. The right coronary artery (RCA) supplies the RV wall, and usually the posterior septum and inferior (diaphragmatic) wall of the LV (posterior LV arteries; 85% of people). The RCA is ‘dominant’ (as opposed to

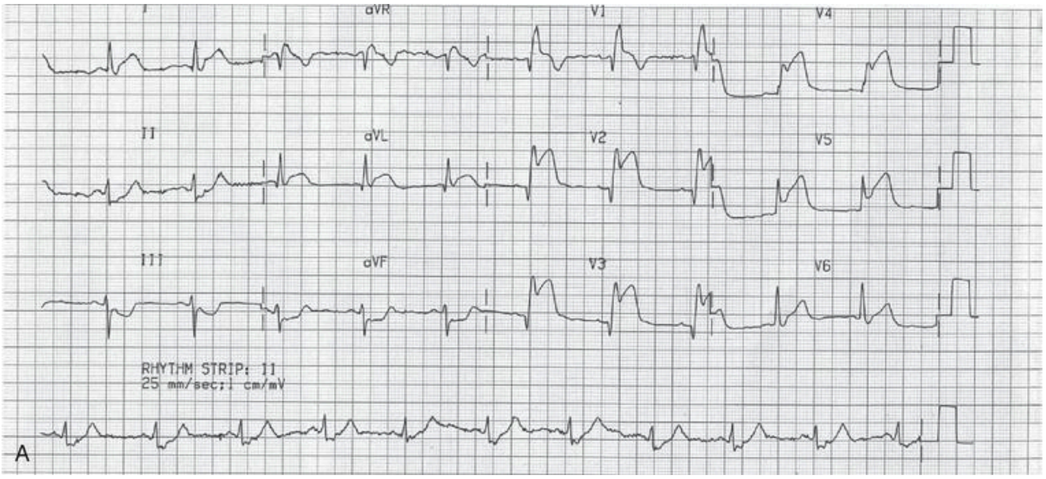
the Cx) if it gives rise to the posterior descending coronary artery and the posterior left ventricular arteries.

Table 29.2

[a] Posterior infarctions are usually identified as lateral on angiography but guidelines suggest that the name be retained. Lack of ST elevation on standard leads may lead to failure to appreciate that they are a STEMI and will benefit from reperfusion therapy. Clinicians should also be aware of novel patterns of ischaemia and ‘STEMI equivalents’ that may include ‘Wellens phenomenon’, STE elevation in aVR, ST changes in the presence of left bundle branch block (LBBB) and the de Winter ST/T complex.

The sensitivity, specificity and predictive value of these patterns in determining the culprit artery (as subsequently determined by angiography) are not perfect. This is especially true of occlusions of the RCA and CX.

CX, Circumflex coronary artery; *LAD* , left anterior descending coronary artery; *RCA* , right coronary artery; *STEMI* , ST-elevation myocardial infarction; *VF* , ventricular fibrillation.



The two-part electrocardiographic recording presents two twelve-lead recordings labelled A and B, each including a rhythm strip for lead two at the bottom. In part A, twelve labelled leads are displayed in standard order across multiple rows. These include limb leads one, two, and three, augmented leads a V R, a V L, and a V F, and chest leads V one through V six. The waveform tracings show complex variations with changes in S T segments, T waves, and Q R S morphology visible across different leads. Below the main leads, a continuous rhythm strip for lead two displays multiple cardiac cycles with distinct intervals and waveforms. In part B, the same twelve leads and rhythm strip are shown, but with visibly different waveform patterns. The rhythm strip in part B presents tall, narrow waveforms repeating at regular intervals. Each part is aligned on a grid with small and large boxes for time and amplitude calibration. A printed label below both rhythm strips shows speed and gain settings marked as 25 millimetres per second and 1 centimetre per millivolt.

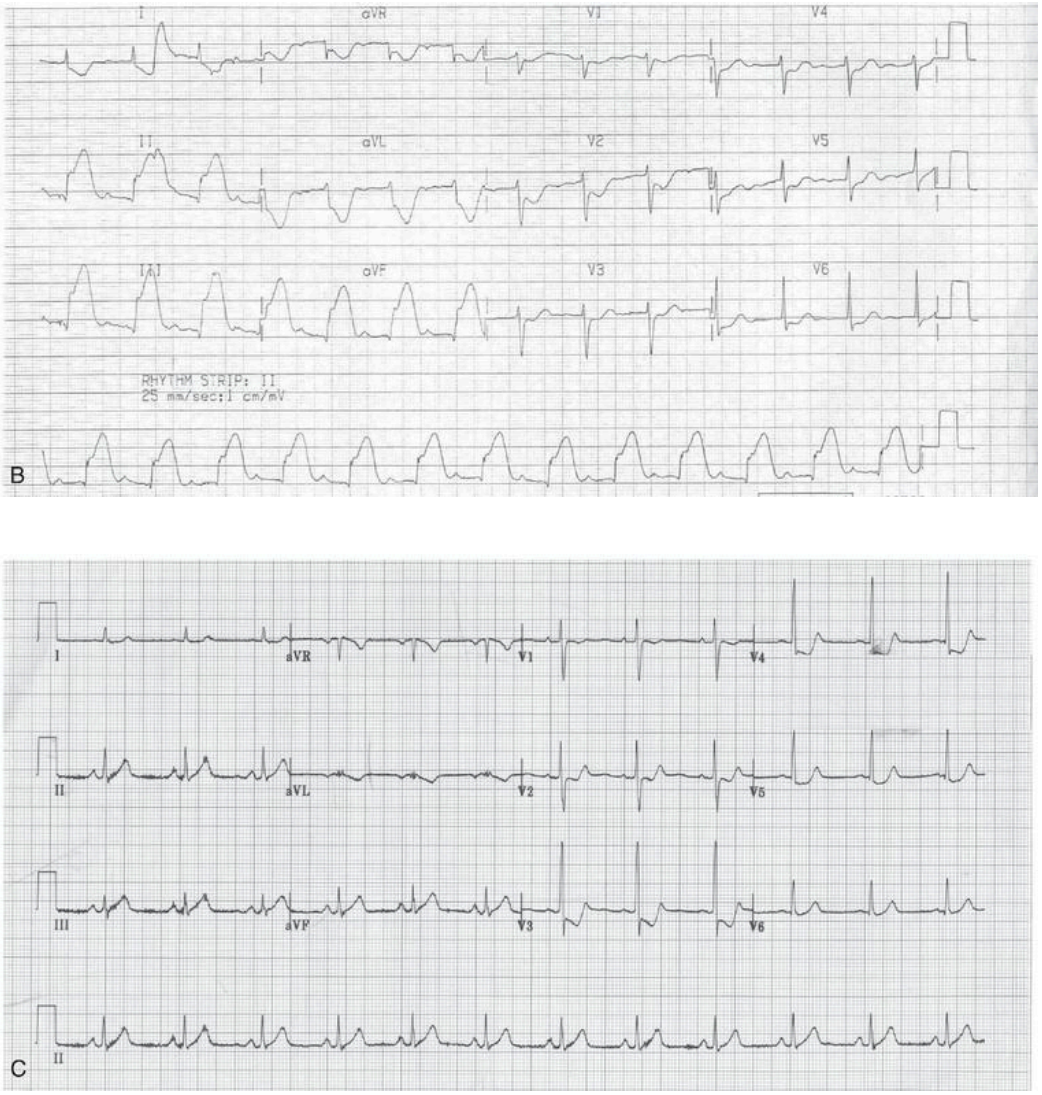


FIG. 29.4 (a) Anterolateral myocardial infarction. There is ST-segment elevation (STE) in anterior leads V2–V6 and lateral leads I, aVL. Reciprocal ST-segment depression in leads II, III and aVF. If within time frames or if shocked, urgent reperfusion is indicated. (b) Inferior myocardial infarction. There is STE in the inferior leads II, III and aVF. Reciprocal ST depression in leads I, aVR, aVL and V2. Subtle ST-depression in V1-V6. The addition of right-sided (V4R) and posterior leads would help identify the presence of right ventricle and posterior infarction (STE). Reciprocal ST-segment depression in leads remote from the site of infarction is a highly sensitive indicator of myocardial infarction. It may be seen in 70% of inferior and 30% of anterior infarctions. (c) Posterior myocardial infarction. There is ST-depression maximal in V2-V4 in keeping with an acute posterior infarct likely from the left circumflex artery. Differentials include

subendocardial ischaemia, although maximal ST-segment depression in the right precordial leads rather than the left precordial leads suggests a posterior infarct. To help differentiate one may conduct an urgent echo and a posterior ECG by placing V7 in left posterior axillary line at the same level as V6, V8 at the tip of left scapula and V9 in the left paraspinal region at the same level as V6. AHA/ACCF/HRS recommendations for the standardisation and interpretation of the electrocardiogram: part VI: acute ischemia/infarction: a scientific statement from the American Heart Association Electrocardiography and Arrhythmias Committee, Council on Clinical Cardiology; the American College of Cardiology Foundation; and the Heart Rhythm Society. Endorsed by the International Society for Computerised Electrocardiology. *J Am Coll Cardiol* . 2009;53(11):1003–1011. doi:10.1016/j.jacc.2008.12.016.

Standard ECGs generally only record from anterior body leads and thus important ECG patterns that must not be missed can be included.[31], [33–35], [42]

- **True or ‘isolated’ or ‘strictly’ posterior wall MI** (3% of MI, although posterior involvement may accompany 15% of STEMI) is important to diagnose as its amount of threatened myocardium is similar to that of inferior MI.[41] It usually causes ‘mirror’ changes in leads V_1–V_2 and although there might be STE in inferior leads II, III and aVF it might not have met diagnostic criteria for reperfusion. Non-standard posterior chest leads (V_7–V_9) usually show STE. Such MIs are usually lateral but the term ‘posterior’ is still retained.[31], [33–35], [42]
- **RV MI** is usually concurrent (20%–60%) with inferior wall MI where suspicious findings include STE in V_1 (overlies the RV), and STE lead III greater than lead II. A V_4R lead may show STE and is sensitive and specific for RV MI, although in 50% of cases, it lasts less than 10 hours.[43] Sinus bradycardia and AV node block may be present.
- Resting ECG changes revealing significant ST-segment depression in six or more body surface leads coupled with STE in aVR and/or V_1 is highly suggestive of **left main coronary artery (LMCA)**

obstruction or **multivessel disease** (severe 3-vessel disease or ‘left main equivalent’).[2,32,33] These changes may even completely disappear when the patient is asymptomatic and should not be ignored.

- The specific pattern of deep T-wave inversion in V_2–V_4 with QT interval prolongation may suggest severe **proximal left anterior descending coronary artery (LAD) disease** . It may occur **after** chest pain but be associated with imminent occlusion.[32,33]
- **A normal ECG** may be present in 15%–20% of NSTEMI, although a normal ECG during pain is unusual.[31,33–35] A small percentage of patients progressively lose R-wave height and develop evidence of Q-waves and a small number progress to CS.

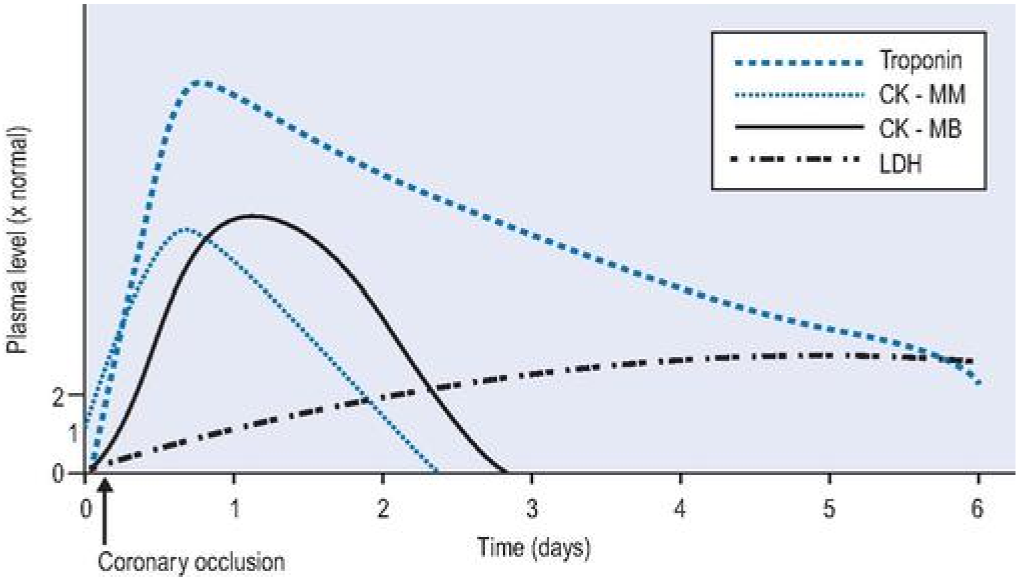
Cardiac Biochemical Markers (Troponins)[7,8,31] (Fig. 29.5)

Cardiac troponins (cTn) can be detected in serum by monoclonal antibodies to epitopes of cTnT and cTnI. These antibodies are highly specific for myocardial, and not skeletal, muscle. Myocardial necrosis produces an initial release of cTn within the cell cytosol. Serum levels are usually detectable 4–6 hours post-MI, with a peak level at 18–24 hours. Return to normal usually occurs over 7–14 days. Renal failure prolongs excretion.

- High sensitivity and specificity have made cTn the gold standard for confirming MI.[7,8]
- cTns should be measured in all patients with ACS. Levels should be taken on arrival and at 3–6 hours. Acute rise and fall help separate ACS from other cTn elevations.
- Elevated levels of cTN in Type 1 MI (see Box 29.1), correlate well with unstable plaque, risk stratification and evidence-based therapies.
- The high sensitivity of cTn means that many people, previously diagnosed in USA, now meet diagnostic criteria for MI.[8,31,34,44]
- Troponins do not differentiate the cause of the myocardial injury (e.g. ischaemia, myocarditis and trauma), thus the clinical context

must always be considered.[7]

- New markers of myocardial necrosis, including cardiac myosin binding protein C (cMyC), and soluble mRNA for vascular cell adhesion molecule-1 and interleukin-6, are currently undergoing clinical evaluation. At the time of writing, cMyC is showing promise as a rapid diagnostic test of myocardial necrosis; however, it has not been implemented in clinical practice.[45]



The graph shows time in days on the horizontal axis, ranging from 0 to 6, and plasma level is expressed as a multiple of normal on the vertical axis. An upward arrow labelled coronary occlusion is placed at time 0. Four separate curves represent different biomarkers. The line labelled troponin rises steeply after occlusion, peaks just before day 2, and gradually declines through day 6. The line labelled C K M B increases rapidly and reaches its peak slightly before day 1, then declines to baseline around day 2. The line labelled C K M M follows a similar pattern, peaking near day 1 and declining shortly after day 2. The line labelled L D H rises more gradually, peaks between day 2 and day 3, and remains elevated through day 6. A key in the upper right corner lists each biomarker along with the corresponding line pattern.

FIG. 29.5 Serum biochemical marker changes after acute myocardial infarction. The sensitivity and specificity of cardiac troponins make them useful for the early diagnosis of myocardial infarction. Their delayed fall may allow diagnosis where presentation

is late. CK or CK-MB is useful if re-infarction with secondary biomarker rise is queried. *LDH,* Lactate dehydrogenase.

The importance of troponins in critical illness is discussed in Chapter 33 .

Echocardiography [46] (See Chapter 25)

Echocardiography is one of the most powerful diagnostic and monitoring tools available to assist with diagnosis and management of ACS. All tertiary ICUs should have 24-hour echocardiography access. [46] Two-dimensional transthoracic (and transoesophageal) echocardiography is used to assess the presence or degree of regional or global LV dysfunction. It identifies regional wall motion abnormalities (RWMAs), helping confirm or exclude the diagnosis of MI in cases where it is uncertain (e.g. left bundle branch block or old MI with atypical presentations). RWMA and loss of wall thickening with contraction are often present in these cases due to ischaemia. [7]

Echocardiography is useful subsequently and in ICU populations to:

- assess infarct size, especially if thrombolysis has interfered with biomarker measurement
- identify RWMA where Tn is elevated but the MI predictive value is uncertain (43% of ICU patients may have an elevated Tn when it is tested) [47]
- rapidly assist differential diagnosis (e.g. aortic dissection and pericardial effusion)
- diagnose specific complications (e.g. MR or papillary muscle rupture, pericardial effusion, myocardial rupture and ventricular septal defect)
- assess mural thrombus and thromboembolic risk
- diagnose RV infarction and infarct extension
- myocardial perfusion scanning using echocardiography is currently an experimental tool but is useful in critically ill patients where coronary angiography is logistically difficult.

Point-of-Care Ultrasound (POCUS) [48, 49]

POCUS is now recognised as an essential first-line and time-critical assessment for cardiac patients with likely ACS. [48] In the emergency department or ICU, the primary purpose of POCUS is to rule out alternative diagnoses, such as aortic dissections, pulmonary embolisms and pericardial effusions. POCUS assessment in the setting of ACS should therefore centre on evaluating [49] :

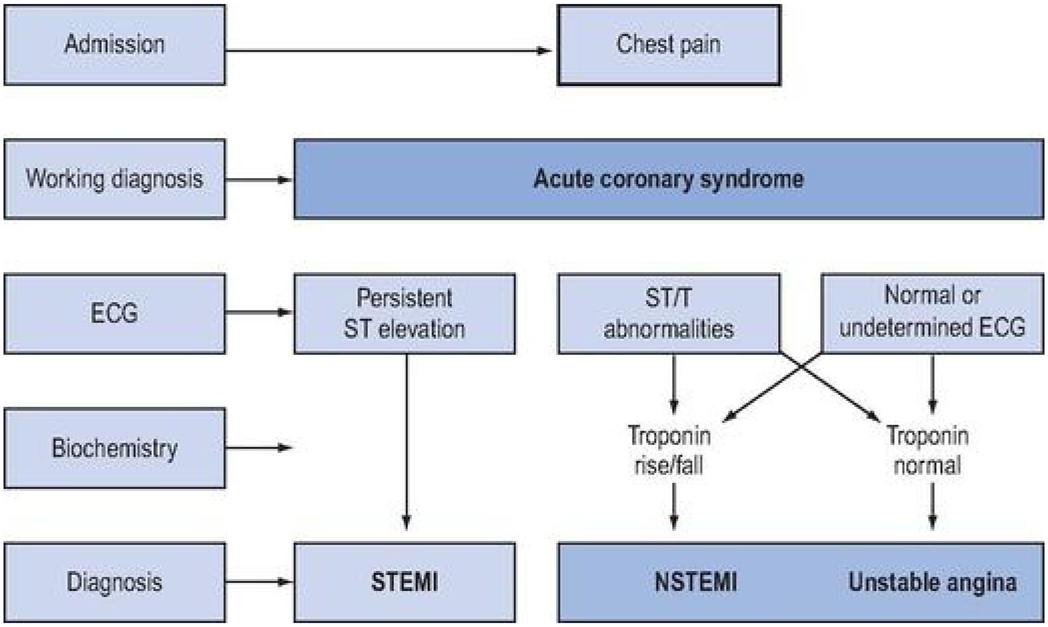
- pericardial effusion
- RV dilation
- overall cardiac function
- absence of pleural sliding
- aortic dilatation and presence of a dissection flap

Considering that assessing RWMAs and wall thickening is one of the more challenging aspects of standard echocardiography interpretation, POCUS should therefore not be used for this primary purpose. [48]

Risk Stratification of Acute Coronary Syndromes (Fig. 29.6) [5, 6]

STEMI

STEMI is the most acutely lethal form of ACS, usually due to complete occlusion of a coronary artery (>90% of patients). [44] It is an indication for immediate reperfusion therapy as successful reperfusion will significantly reduce the size of the evolving MI, although some troponin rise is inevitable. Patients who develop STE after admission should also receive reperfusion therapy.



Admission
Chest pain
Working diagnosis
Acute coronary syndrome
ECG
Persistent ST elevation
ST/T abnormalities
Normal or undetermined ECG
Biochemistry
Troponin rise/fall
Troponin normal
Diagnosis
STEMI
NSTEMI
Unstable angina

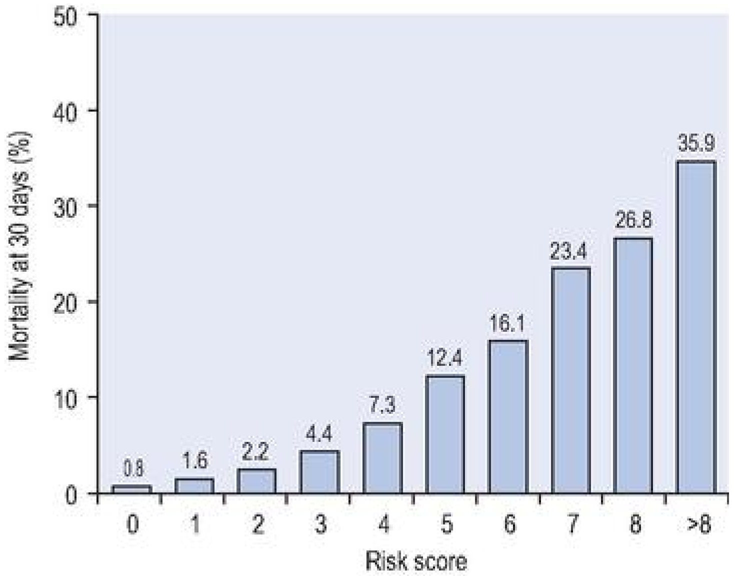
The flowchart shows the process for diagnosing acute coronary syndrome following hospital admission with chest pain. The sequence begins with admission for chest pain. A working diagnosis is initiated for acute coronary syndrome. The first step is recording through an electrocardiogram, which leads to persistent S T elevation, which connects directly to the diagnosis of S T E M I. The second step leads to checking S T or T wave abnormalities, followed by determining troponin rise or fall, which leads to diagnosis of N S T E M I. If troponin is normal, it leads to the diagnosis of unstable angina. The third step leads to a normal or undetermined electrocardiogram. This leads to determining if troponin is normal, which further leads to a diagnosis of unstable angina. If troponin has a rise or fall, it leads to diagnosis of N S T E M I. The determination of the status of troponin is labelled under biochemistry.

FIG. 29.6 The spectrum of ACS. Physicians should obtain, interpret and stratify patients with ACS within 10 minutes of arrival. STE in this clinical setting is usually due to complete coronary occlusion and most patients will ultimately have some biomarker elevation (STEMI). Rapid and sustained coronary artery reperfusion (PCI or thrombolytic therapy) may significantly decrease myocardial damage. Well-organised systems of care should be in place to minimise delays. In patients without STE (non-STEACS), serial biomarker measurements may define those patients with elevated levels (NSTEMI) and those with ACS but normal biomarkers (unstable angina). Clinical review and further tests may lead to a non-ischaemic cause of chest pain in some patients. Subsequent echocardiography and imaging may help define the extent of injury, coronary anatomy pathology and its clinical importance. *ACS* , Acute coronary syndrome; *ECG,* electrocardiogram; *NSTEMI* , non–ST-elevation myocardial infarction; *PCI* , percutaneous coronary intervention; *STEMI* , ST-elevation myocardial infarction. (Adapted from Collet JP, Thiele H, Barbato E, et al. 2020 ESC Guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. *Eur Heart J* . 2021;42(14):1289–1367. https://doi.org/10.1093/eurheartj/ehaa575 'Adapted with permission of Oxford University Press (UK) © European Society of Cardiology' http://www.escardio.org/guidelines.

At the commencement of the thrombolysis era, left bundle branch block (LBBB) was also recognised as gaining the largest benefit from thrombolysis. Unless the LBBB could be proven old, previous sentinel guideline suggestions were that it be *'presumed new'* and thrombolysis be administered. [50] The updated 2013 STEMI guidelines suggest a more prudent approach, with LBBB no longer recommended as an equivalent to STEMI with planned emergent reperfusion therapy. [2]

Ageing populations with more co-morbid illness, see such 'not known to be old' LBBB, arrival ECGs, present in 2%–9% of ACS emergency admissions. [51–53] However, only one-third of patients presenting with LBBB is found to have a STEMI ACS (occluded culprit artery), one-third have non-ACS cardiac disease, and up to one-third have non-cardiac illness. [54] Concerns of 'missed diagnosis' and of thrombolysis risk, see many referred for angiography. Whilst 'false activations' of a catheter laboratory for ACS might be less than 14%, in this LBBB setting it may be 44%. [51] Strategies for improvement include rapid senior cardiology review, urgent echocardiography and telemedicine or ECG reviews. The Sgarbossa ECG criteria are specific but have low sensitivity, and views on their value vary.[51], [52]

Considerable variability in mortality risk exists among patients with STEMI. Readily available bedside clinical risk score tools may give insight into predicted 30-day mortality (Fig. 29.7).[55] The addition of in-hospital complications data may allow hospital discharge, longer term, 1-year prognostication after STEMI (Dynamic TIMI Risk Score).[56]



At risk (%)	12	22	16	16	14	9	8	3	2	1

One point each of:	· Age 65–74 / ≥75 years	2/3 points
	· SBP <100	3 points
	· Heart rate >100	2 points
	· Killip II–IV	2 points
	· Anterior STE or LBBB	1 point
	· Diabetes, h/o HTN or h/o angina	1 point
	· Weight <67 kg	1 point
Possible score 0–14	· Time to Rx >4 hours	1 point

The bar graph shows mortality at 30 days on the vertical axis and risk score on the horizontal axis. The horizontal axis ranges from 0 to greater than 8, and the vertical axis ranges from 0 to 50 percent. Each vertical bar represents a specific risk score and the corresponding mortality percentage. The mortality values increase as follows, score 0 is 0.8 percent, score 1 is 1.6 percent, score 2 is 2.2 percent, score 3 is 4.4 percent, score 4 is 7.3 percent, score 5 is 12.4 percent, score 6 is 16.1 percent, score 7 is 23.4 percent, score 8 is 26.8 percent, and scores greater than 8 reach 35.9 percent. A row showing the percentage of patients at each risk score level is below the graph, starting with 12 percent at score 0 and decreasing progressively to 1 percent for scores greater than 8.

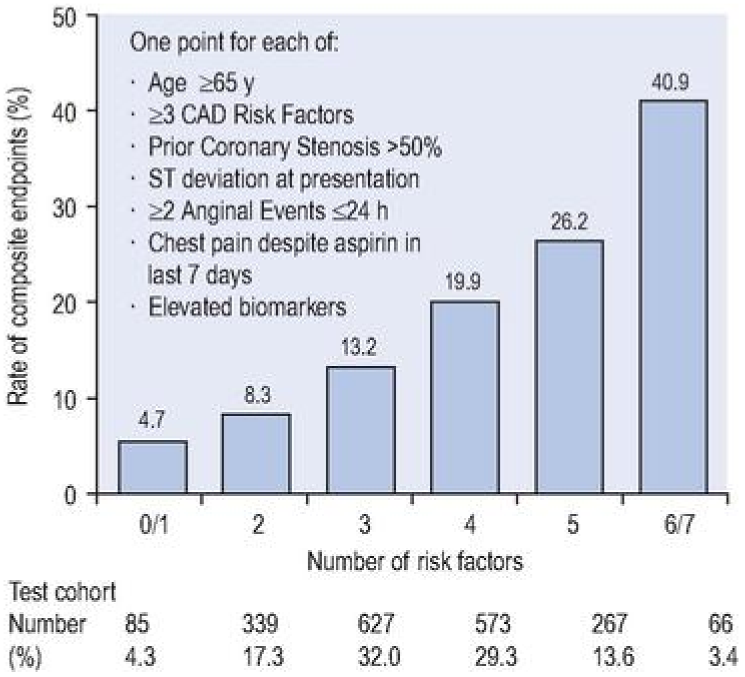
Additional details include scoring guide explaining how clinical features contribute to the total score. One point is assigned for each of the following criteria, age between 65 and 74 years, systolic blood pressure less than 100, heart rate above 100, Killip class between two and four, presence of anterior S T E or left bundle branch block, diabetes or history of hypertension or history of angina, weight less than 67 kilograms, and time to treatment longer than 4 hours. Age 75 years or older contributes two-thirds of a point. Systolic blood pressure less than 100 adds three points. Heart rate above 100 adds two points. Killip class between two and four adds two points. The total possible risk score ranges from 0 to 14.

FIG. 29.7 STEMI-TIMI: TIMI (thrombolysis in myocardial infarction) risk score for STEMI is a simple bedside evaluation for predicting 30-day mortality. *h/o,* History of; *HTN* , hypertension; *LBBB* , left bundle branch block; *SBP* , systolic blood pressure; *STE* , ST elevation; *STEMI* , ST-elevation myocardial infarction. (With permission from Morrow DA, Antman EM, Charlesworth A, et al. TIMI risk score for ST-elevation myocardial infarction: a convenient, bedside, clinical score for risk assessment at presentation. *Circulation* . 2000;102(17):2031–2037.)

NSTEACS

Patients may have ischaemic chest pain but have ‘non-specific’ ECG changes (normal, ST-segment depression or minimal elevation or T-wave inversion). After serial biomarker testing, these patients will later prove to have either USA (Tn normal) or NSTEMI (Tn elevated). In contrast to patients with STEMI, thrombolysis in patients with ST depression or normal ECGs was associated with increased mortality.[36,50] Only 35%–75% of patients have evidence of ‘significant’ coronary thrombus formation.[44,50,57] Of note, some myocardial regions may have few ‘facing ECG leads’; for example, 27% of inferolateral NSTEMI may actually be demonstrated to have occluded culprit arteries and, if detected, an early invasive management strategy should be established. [58]

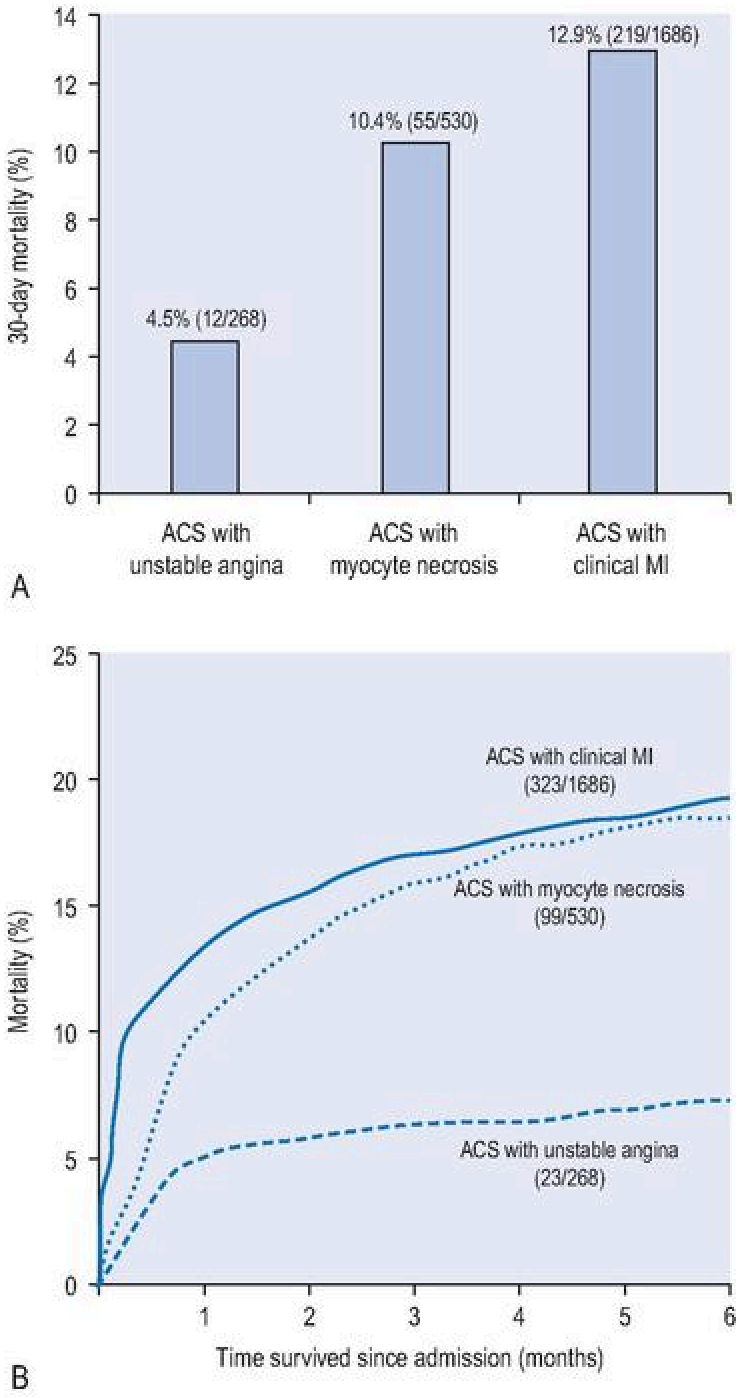
NSTEMI therapy aligns more clinically with that of USA than with that of STEMI. These two conditions, comprising NSTEACS, represent a spectrum of diseases with common treatments directed at platelet inactivation and ‘plaque stabilisation’. Despite the heterogeneous nature of this group of patients, and variable prognoses, early stratification using ECGs, troponins and simple clinical variables may define risk and guide evidence-based therapy (Fig. 29.8). [59] The more severe the ischaemia, the stronger the indication for more aggressive anticoagulation and invasive procedures.



The bar graph plots the number of risk factors on the horizontal axis and the rate of composite endpoints in percent on the vertical axis, which ranges from 0 to 50 percent. Seven vertical bars represent groupings based on the number of risk factors, labelled as 0 or 1, 2, 3, 4, 5, and 6 or 7. The height of each bar increases progressively with the following percentages shown at the top of each bar: 4.7 for 0 or 1, 8.3 for 2, 13.2 for 3, 19.9 for 4, 26.2 for 5, and 40.9 for 6 or 7. To the left of the graph is a list stating that one point is assigned for each of the following risk factors, age 65 years or older, presence of three or more C A D risk factors, prior coronary stenosis greater than 50 percent, S T deviation at presentation, two or more anginal events within 24 hours, chest pain despite aspirin taken within the past 7 days, and elevated biomarkers. A horizontal section labelled test cohort is below the graph, listing the number of patients in each group along with the percentage representation, starting from 85 patients at 4.3 percent for 0 or 1 risk factor and ending at 66 patients at 3.4 percent for 6 or 7 risk factors.

FIG. 29.8 NSTEMI-TIMI: the thrombolysis in myocardial infarction (TIMI) score is used to estimate the risk of the composite end-point of death, myocardial infarction, or need for urgent cardiac catheterisation (vertical axis) at 14 days in patients with unstable angina or NSTEMI. Each risk factor is worth 1 point for a maximum score of 7. *CAD* , Coronary artery disease; *NSTEMI* , non–ST-elevation myocardial infarction. (Adapted from Antman EM, Cohen M, Bernink PJ, et al. The TIMI risk score for unstable angina/non-ST elevation MI: a method for prognostication and therapeutic decision making. *JAMA* . 2000;284(7):835–842.)

Fig. 29.9A [57,60] displays the higher mortality of STEMI patients (compared to patients presenting with and without STE) present in the hospital, and at 6 months, despite lower early, in-hospital mortality in NSTEACS patients. Fig. 29.9B [57,60] shows that the subsequent rates of ongoing fatal events may be higher.



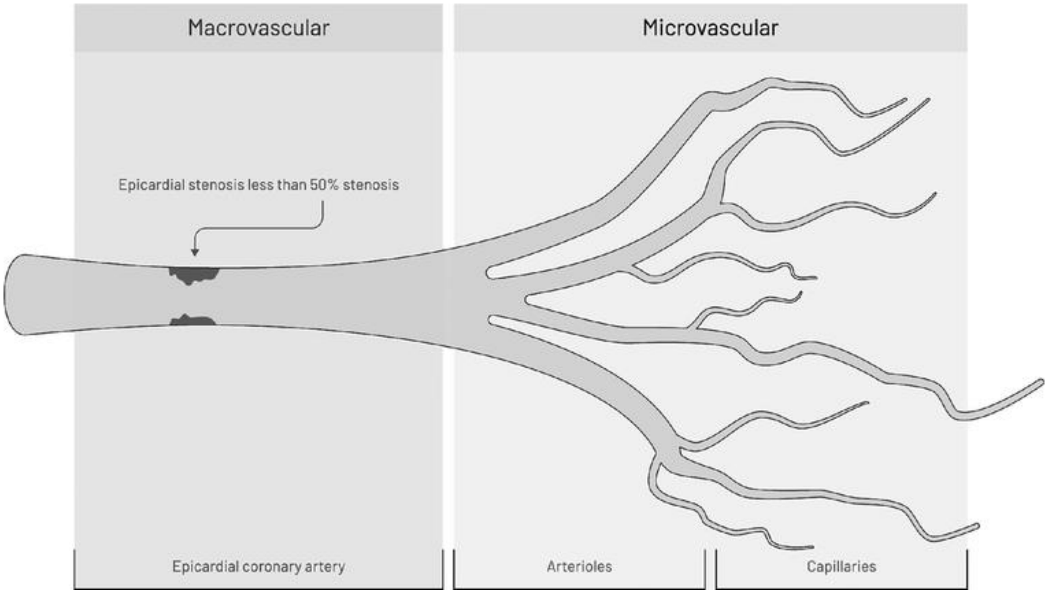
The two-part graph is labelled A and B. Part A displays a vertical bar graph with 30-day mortality on the vertical axis and three categories of acute coronary syndrome on the horizontal axis. The categories are acute coronary syndrome with unstable angina, acute coronary syndrome with myocyte necrosis, and acute coronary syndrome with clinical myocardial infarction. The bars show progressively increasing mortality percentages: 4.5 percent for unstable angina with 12 deaths among 268 patients, 10.4 percent for myocyte necrosis with 55 deaths among 530 patients, and 12.9 percent for clinical myocardial infarction with 219 deaths among 1686 patients. Part B presents a line graph showing mortality percentage on the vertical axis and time survived since admission in months on the horizontal axis, ranging from 0 to 6 months. Three survival curves represent the same categories. The lowest line corresponds to unstable angina, gradually rising to just above 5 percent with a final count of 23 deaths among 268 patients. The middle line corresponds to myocyte necrosis, reaching nearly 19 percent with 99 deaths among 530 patients. The uppermost line corresponds to clinical myocardial infarction, ending at around 22 percent with 323 deaths among 1686 patients. All lines show a sharp rise in mortality within the first two months, followed by slower increases through month 6.

FIG. 29.9 (a) Thirty-day mortality according to the British Cardiac Society category. (b) Kaplan–Meier survival area curves for events from admission to 6 months. *ACS* , Acute coronary syndrome; *MI* , myocardial infarction. (Reproduced from Das R, Kilcullen N, Morrell C, et al. The British Cardiac Society Working Group definition of myocardial infarction: implications for practice. *Heart* . 2006;92:21–26, with permission.)

Myocardial Infarction With No Obstructive Coronary Disease (MINOCA)

With the advent of increasingly sensitive troponins, there is a subset of patients who present with an MI but have no discernable angiographic obstruction of >50% stenosis in one of the main epicardial vessels (i.e. MINOCA). [7] MINOCA account for between 5% and 10% of all MIs and include coronary, cardiac and extra-cardiac causes. [61] Coronary causes consist of coronary artery spasm and microvascular dysfunction, whereas cardiac causes consist of myocarditis and Takotsubo syndrome. Examples of extra-cardiac causes include sepsis, renal failure and pulmonary embolisms.

Coronary microvascular dysfunction (CMD) is a significant contributor to all of the above causes of MINOCA. [62] CMD is the term used to characterise structural and functional abnormalities of the coronary microcirculation that result in angina and myocardial ischaemia. [63] The coronary microcirculation that cannot be seen on coronary angiography (Fig. 29.10) comprises prearterioles, arterioles and capillaries and has a diameter of less than 200 µm [64] and is responsible for 80% of the resistance in the coronary circulation. [65] CMD can be caused by any alteration in the structure or function of the microcirculation resulting from impaired vasodilation, microvascular spasm or luminal narrowing of the coronary microcirculation due to perivascular fibrosis. [62]



Macrovascular
Microvascular
Epicardial stenosis less than 50% stenosis
Epicardial coronary artery
Arterioles
Capillaries

The labelled vascular diagram shows a branching vascular structure divided into two regions. The left half is labelled macrovascular and includes a thick central vessel marked as epicardial coronary artery. Two narrowing within this vessel are labelled as epicardial stenosis less than 50 percent stenosis. The artery branches progressively toward the right side of the diagram, labelled microvascular. This region contains multiple thinner vessels branching into smaller structures labelled arterioles and then into finer branches labelled capillaries. Each anatomical section is separated vertically with labels at the top and bottom identifying the corresponding vascular category and structure. The diagram depicts transition from a large coronary artery through intermediate vessels to the smallest microcirculatory elements.

FIG. 29.10 The coronary microcirculation.

Diagnosis of CMD can be either through invasive or non-invasive techniques. Invasive assessment through coronary angiography can exclude obstructive epicardial coronary disease as well as conduct a comprehensive assessment of the coronary microcirculation, including coronary flow reserve and microvascular resistance.[62]

Non-invasive techniques include positron emission tomography (PET), which is the gold standard for CMD, cardiac magnetic resonance (CMR) and transthoracic Doppler echocardiography.[62] CMR combined with pharmacological stress testing and gadolinium tracer can comprehensively assess for CMD.[66] Nonetheless, its inaccessibility and expense constitute a significant barrier. Alternatively, transthoracic Doppler echocardiography, whilst able to measure coronary blood flow in the epicardial vessel at rest and during hyperaemia, has the advantages of being readily available and less expensive to administer.[66] However, the caveat to all non-invasive assessments includes the need to exclude epicardial coronary disease before confirming the diagnosis of CMD. Therefore computed tomography coronary angiography is often an adjunct assessment to non-invasive assessment.[66]

Immediate Management of Acute Coronary Syndromes

Pre-hospital Care

A total of 50% of deaths from MI occur within the first hour of symptom onset. These deaths are usually due to ventricular fibrillation (VF). Treatment is defibrillation.

Immediate Hospital Care

1. Cardiac monitoring.
2. Oxygen supplementation[28,67] (2–4 L/min via facemask or nasal prongs) is recommended for breathless or hypoxic patients (<94%). Administration to non-hypoxic patients has not been shown to have a beneficial effect on 12-month all-cause mortality.[2,68,69]

3. ECG (12-lead) should be taken within 10 minutes of arrival and regularly thereafter. Pre-hospital ECGs have been shown to have a favourable effect on outcome, mediated through shorter times to thrombolysis and primary PCI.[67]
4. Aspirin at 160–325 mg (not slow release) should be chewed or dissolved, and swallowed, then continued at a dose of 75–100 mg/day, with the recommended dose of aspirin in patient on dual antiplatelet therapy (DAPT) being 81 mg.[70] International guidelines have some differences in their recommended doses, guiding regional practice.[71] Aspirin reduces mortality and complications of MI with minimal side effects.[2,6,26,71,72] Clopidogrel or prasugrel is given if there is aspirin sensitivity or high risk.[28,44] DAPT with ticagrelor or prasugrel added to aspirin is the standard treatment for ACSs.[4] Clopidogrel which is classed as less potent and with variable inhibition should be considered only if ticagrelor and prasugrel are contraindicated, not available or following fibrinolytic therapy.[70] In the most recent European ACS guidelines (2023), patients whose working diagnosis is a STEMI may receive pre-treatment with a second antiplatelet medication such as ticagrelor (Class IIb).[29] However, for patients with a working diagnosis of NSTEACS, pre-treatment with a second antiplatelet therapy before knowing the coronary anatomy is not recommended (Class IIIa).[29]
5. Sublingual glyceryl trinitrate (GTN) given by spray may provide symptomatic relief of active chest pain. Side effects include headache. Hypotensive reactions and a hypotensive bradycardic response (the Bezold–Jarisch reflex) can occur. Recent phosphodiesterase inhibitor use (e.g. sildenafil) should be excluded.
6. Venous access is usually established.
7. Pain relief must be provided.[26] Pain produces catecholamines, which increase ischaemia. Reassurance and small incremental, titrated boluses of intravenous (IV) morphine (1–2 mg) or fentanyl (20–40 µg), can be given. A concern is that gastric emptying delay, or vomiting, may interfere with the absorption of antiplatelet

agents. Admission of non-steroidal anti-inflammatory drugs (NSAIDs) should be ceased immediately, as use in the week prior to admission is associated with increased risk of death and cardiac complications at 6 and 30 days.[44,73] Pain relief is best served by rapid reperfusion.

8. Rapidly identify ACS patients with STE (Box 29.4).[2,28,67,74] Reperfusion is critically time dependent (‘time is muscle’).
9. Emergent primary PCI (or rapid transfer to a PCI centre) is generally superior to thrombolytic therapy.[75] Thrombolysis should be performed where the benefits of urgent primary PCI cannot be obtained.
10. Pulmonary oedema is treated with upright posture, sublingual or IV nitrates and if moderate to severe, with continuous positive airway pressure (CPAP) ventilation. Response to IV furosemide has slow onset and may be variable depending upon volume status.
11. Beta-adrenergic blockers (oral) should be commenced in haemodynamically stable patients as soon as possible (usually after thrombolytic therapy has been given or before PCI), but only where there are no contraindications.[2]
12. Prophylactic antiarrhythmics are *not* administered, but all patients should be monitored with rapid access to defibrillation.

Box 29.4

Typical indications for reperfusion therapy in acute myocardial infarction

Reperfusion therapy

Presentation ≤12 hours with acute coronary syndrome (ACS), unrelieved by sublingual nitroglycerine *and*

New ST-segment elevation in two or more contiguous leads with the cut-off points:

≥0.2 mV in men, >0.15 mV in women in leads V_2–V_3 and/or

≥0.15 mV in other leads, *or*

New-onset LBBB (include presumed new-onset), *or*

Posterior infarction (dominant R-wave and ST depression ≥2 mV in V_1–V_2), or

Presentation 12–24 hours after onset of ACS with continuing pain and evidence of evolving infarction

Posterior myocardial infarction is an important presentation of STEMI where STE is not present in standard chest leads. STEMI (2%–4% of cases) may present with new or presumed new LBBB, although many such patients will not have an occluded culprit artery favouring PCI over thrombolysis. International guidelines[4,6,26] may vary in definitions,[71] with some having a more conservative response to LBBB.[71]

From Neeland IJ, Kontos MC, de Lemos JA. Evolving considerations in the management of patients with left bundle branch block and suspected myocardial infarction. *J Am Coll Cardiol*. 2012;60(2):96–105.

Acute Management of STEMI (Fig. 29.11)[2,28,76]

Reperfusion Therapy

Prompt reperfusion therapy (mechanical or pharmacological), to establish coronary artery flow is the gold standard for STEMI treatment and is far superior to non-reperfusion (‘conservative’) management. It should be considered for all patients presenting within 12 hours of STEMI onset.[2,28,77]

*The time point the diagnosis is confirmed with patient history and ECG ideally within 10 min from the first medical contact (FMC).
All times are related to 'FMC' (first medical contact).

The flowchart presents a clinical decision for managing S T E M I diagnosis. The process begins with a confirmed diagnosis of S T E M I. From there, two branches emerge. The left branch applies to patients at a primary P C I capable centre, where the preferred time to intervention is less than 60 minutes. This leads to a step labelled primary P C I. If primary P C I is not performed, the next step is rescue P C I. If rescue P C I is not immediately required, the path continues to successful fibrinolysis. If fibrinolysis is successful, coronary angiography is performed preferably between 3 and 24 hours. If not successful, immediate P C I is initiated. The right branch applies to patients at an E M S or non-primary P C I capable centre. The next decision step asks if P C I is possible in less than 120 minutes. If yes, the patient is transferred immediately to a P C I centre, preferably within 90 minutes or within 60 minutes for early presenters. If no, the next step is immediate fibrinolysis, followed by transfer to a P C I centre. All times are referenced from the first medical contact. A footnote explains that the diagnosis is confirmed with patient history and electrocardiogram, ideally within 10 minutes from first medical contact.

Modified with permission of Oxford University Press (UK) © European Society of Cardiology.)

Both primary PCI and thrombolysis (fibrinolysis) are proven treatments with maximal benefit being achieved when performed early. Age is strongly related to mortality, often reflecting co-morbid illness.[59, 78] Underrepresentation of elderly in trials has left questions about best practices. Their large numbers (30% of ACS are >75 years) and high risk, identifies the elderly as a group where aggressive intervention offers significant potential benefit.[78] Both observational trials and RCTs have demonstrated that among patients over 75 years, revascularisation by PCI or CABG was associated with reduced rates of major adverse cardiac events (MACE) and mortality.[79–81]

Reperfusion reduces infarct size, preserves LV function, reduces mortality and prolongs survival.[82] Strategies to achieve reperfusion can include:

- PCI (e.g. angioplasty, usually with stent insertion)

- thrombolytic therapy
- urgent CABG.

Primary percutaneous coronary intervention [2, 28, 74, 76]

- Primary PCI delivered in centres of excellence and without transfer delay, was far superior to thrombolysis, with reduced short-term mortality (5% vs. 7%), non-fatal re-infarction (3% vs. 7%) and stroke (1.0% vs. 2.0%). The combined trial end-point of short-term mortality, non-fatal re-infarction and stroke was lower in the primary PCI group (8% vs. 14%) [83, 84]
- Current data suggest that thrombolysis produces an ***absolute reduction*** in 30-day mortality of 4% and that primary PCI is a further 1.5%–2% better. [77]
- Current data suggests thrombolysis has a 2% risk of stroke (number needed to harm, 50), and primary PCI technique has a 1% risk of stroke. [77]

Emergency PCI can be divided into:

- primary PCI
- *rescue PCI* after failed thrombolysis
- *pharmaco-invasive PCI* (thrombolysis with routine transfer to PCI centre for assessment) [85]

Immediate, urgent PCI when available in STEMI is strongly indicated in patients with [28, 44, 76]:

- presentation to cardiological centres of excellence
- contraindications to thrombolysis (e.g. bleeding risk) presentation greater than 12 hours
- uncertain diagnosis (e.g. pericarditis and LBBB)
- high-risk but predicted low benefit from thrombolytic therapy (e.g. elderly, diabetic and with presentation >3 hours)
- Cardiogenic shock even up to 12–36 hours post-MI [86]

- previous CABG.

Contraindications to primary PCI are uncommon, the major risk factor being complications from obligatory adjunctive antiplatelet or antithrombin therapy. Caution is needed in those at risk of contrast-associated renal failure. [82, 87] Primary PCI is limited by the risk of abrupt vessel closure (early), and late thrombosis and stenosis. Coronary stenting reduces restenosis risk. [88]

Thrombolytic therapy

Thrombolytic therapy (in absence of contraindications) should be given to patients with STEMI and onset of ischaemic symptoms within the previous 12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact. [2, 28, 29] Better outcomes from primary PCI have significantly decreased the percentage of people receiving thrombolysis, although, in much of the world, it remains a cost-effective and essential treatment. [85] Outcomes are critically dependent upon time from symptom onset (‘The Golden Hour’).

Thrombolytic agents [89, 90]

1. *Non–fibrin-specific:* These catalyse systemic fibrinolysis (e.g. streptokinase [SK]).
2. *Fibrin-specific:* These produce limited plasminogen conversion in the absence of fibrinogen. Current agents include alteplase (rt-PA), reteplase (r-PA) and tenecteplase (TNKase)

The abovementioned grouping is based on the *pharmacology* and physiology of agents. A historical grouping by *‘generations’* outlines clinically driven need for agents to achieve the best patient outcomes.

The ***first-generation*** fibrinolytic agent SK, formed complexes with plasminogen, releasing the protease plasmin which created a systemic lytic state. ‘Fresh’ local coronary thrombus was lysed, significantly reducing mortality. Low systemic fibrinogen levels and a lytic state, however, were associated with a 0.6% incidence of lethal or disabling cerebral haemorrhage, which was higher in the elderly. SK became the agent against which newer ***second-generation*** **'fibrin-specific' agents,** provided more localised coronary artery clot lysis. Trials of rt-PA (alteplase) versus SK found a 1% mortality reduction (6.3% vs. 7.4%) at 30 days. [90] Outcomes were superior, but complex infusion rates and doses could be problematic. ***Third-generation*** agents have been trialled against second-generation agents on a 'non-inferiority basis' to improve safety and efficacy. Reteplase and tenecteplase (TNKase) enjoy simpler administration, more fibrin specificity, less allergenicity and more resistance to the plasminogen-activator inhibitor. The shorter duration of action of the fibrin-specific agents often requires early administration of unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH). [28]

Major and minor contraindications are shown in Table 29.3 .

Table 29.3

Specialist advice should be sought urgently where doubt exists and PCI is not available. Patients with contraindication may still benefit from urgent PCI and indeed it is usually the preferred option. PCI is generally the desired treatment in all of the above. *CPR* , Cardiopulmonary resuscitation; *CVA* , cerebrovascular accident; *INR* , international normalised ratio; *PCI* , percutaneous coronary intervention.

Side effects and choice of agent [28], [82]

Bleeding complications are the most serious thrombolysis complication. Approximately 1% of patients may suffer early cerebral haemorrhage but this figure can be 4% in high-risk populations. Risk factors are advanced age, significant admission systolic and diastolic hypertension, female gender, prior cerebrovascular disease and low weight. Major non-cerebral bleeds requiring transfusion or significant intervention may occur in 4%–13% of patients.

Failure to adjust the dose of fibrinolytic correctly to body weight may be associated with increased mortality and intracerebral haemorrhage. Guidelines outline similar caution with weight-based dosing of heparins.

Thrombolytic therapy with streptokinase in the Aboriginal population should also not be used. Australian Aboriginals are more likely to have anti-streptokinase antibodies (75% prevalence) than non-indigenous populations.[91] High anti-streptokinase antibody titres have been demonstrated to inhibit streptokinase activity.[92]

Primary PCI Versus Thrombolytic Therapy

Duration of symptoms, and time to achieve transfer, are critical.[82, 93] Advantages of more reliable revascularisation from PCI can be lost if transfer is not expedient and if the delay is more than 60–120 minutes.[82, 93] The importance of transfer for an individual patient will vary significantly depending upon the baseline risk. Many patients present to centres that do not offer primary PCI. Given the superiority of PCI over thrombolysis, transfer to such a centre has significant benefits.

- Thrombolysis is the most effective treatment in patients with low bleeding risk and with arrival soon after symptom onset. Current outcomes from thrombolytic therapy in patients presenting early (≤3 hours post-onset), and PCI not on-site or immediately available, are very good as fresh clots seem more likely to be lysed.
- Such benefits of thrombolysis are not present in those who present later (≥3 hours after symptom onset) or who have a high risk of bleeding or another contraindication to thrombolysis.[82, 93]

Invasive strategy (PCI) is generally superior to thrombolysis if[44]:

- ineligible for thrombolytic therapy (see Table 29.3)
- cardiogenic shock or severe heart failure, Killip Class ≥3
- significant ventricular arrhythmias
- skilled PCI lab is immediately available with surgical backup:
    - first medical contact-to-balloon or door-to-balloon is less than 90 minutes
    - door-to-balloon time minus door-to-needle time less than 60 minutes

- transfer can be achieved in less than 120 minutes and ideally less than 60 minutes
- diagnosis is uncertain (apical ballooning syndrome, myocarditis and aortic dissection)

Other indicators that transfer to an expert centre for PCI should be considered are:

- elevated risk from STEMI, advanced age [94]
- extensive anterior infarction with late presentation (symptom onset ≥3 hours)
- high risk of bleeding, symptom onset more than 3 hours
- previous MI or CABG

Thrombolysis may be preferred if [28, 44, 82]:

- transfer to a centre for primary PCI may be harmful to patients where:
  - early presentation (≤3 hours, delay to invasive strategy)
  - invasive strategy not available

Combinations of Treatments: Thrombolysis and Primary Percutaneous Coronary Intervention [44, 74, 82, 85, 95, 96]

In patients with failed thrombolysis, further thrombolysis is not beneficial and may cause harm. [97] Urgent transfer to a PCI centre is required, and **‘rescue angioplasty’** has shown a significant, lower combined end-point of death, re-infarction and HF, but with bleeding risk. [2, 28, 29, 77] Immediate, routine early PCI of all thrombolysed patients (<3 hours) could not guarantee benefit because of frequent bleeding. The transfer of all patients after thrombolysis, for reassessment and then ‘optimally timed’ PCI (usually within 3–24 hours or before discharge) on a case-by-case basis, is beneficial. [2, 28, 77, 98] Trials of administration of reduced doses of thrombolytic or antithrombotic loading to ‘facilitate’ immediate PCI, have not shown benefit. [94, 97, 99–101] For patients with late-onset CS, time frames for benefit from ‘rescue PCI’ may be extended.

Adjunctive Therapy Used With Reperfusion Treatments [87, 102]

Early adjunctive therapy is necessary with thrombolysis (and PCI) as at infusion completion, 50% of patients may not have TIMI 3 flow. Antithrombin agents facilitate ongoing ‘catch-up’ lysis and with antiplatelets, may decrease re-occlusion of unstable arteries. DAPT (with aspirin and clopidogrel) should be co-administered at the time of thrombolysis. [29, 103] In addition, anticoagulation therapy is advised for patients who have undergone thrombolysis until revascularisation or for up to 8 days if not revascularised. [29] The underlying coronary artery remains unstable during the following year, evidenced by angiographic re-occlusion in 30% and recurrence of ischaemia in 20%. [102] Coronary arteries that have been dilated or stented, may similarly remain unstable. Immediate (early) adjunctive therapies are directed at platelet aggregation and coagulation pathways. Further therapies are directed at ‘plaque stabilisation’, myocardial ischaemia and arrhythmias. Advances in adjunctive reperfusion therapies have been a major driver of outcome improvements.

Aspirin [28, 44, 104, 105]

Aspirin remains the most cost-effective short- and long-term treatment for STEMI and ACS. Unless contraindicated, aspirin should be administered to all patients with STEMI [2] and should be continued indefinitely. [2] In the Second International Study of Infarct survival (ISIS-2), aspirin reduced absolute mortality by 2.4% with ~50% RRR in re-infarction and stroke, and without an increase in cerebral haemorrhage or bleeds requiring transfusion. [72, 106–108] Higher doses of aspirin do not provide better outcomes and may in fact be associated with higher event rates. [105, 109]

Aspirin also benefits patients who have not or cannot receive reperfusion therapy. [87] Aspirin-allergic patients benefit from other antiplatelets such as clopidogrel (avoid if the patient has had a previous transient ischaemic attack or cerebrovascular accident).

Despite the extreme value of aspirin, there have been major advances in new agents and therapy.

Dual Antiplatelet Therapy [2, 104, 105, 110]

The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) Trial [111] demonstrated the benefits of adding a second antiplatelet agent to aspirin (DAPT). The addition of clopidogrel to aspirin in USA and NSTEMI saw a 20% reduction in composite events, evident within 24 hours and continued over 12 months without prohibitive bleeding. Benefits of dual clopidogrel and aspirin have been demonstrated in STEMI patients undergoing PCI, and in thrombolysed STEMI patients, both with and without subsequent stenting. [105] The current standard of care for ACS patients includes aspirin and an ADP-receptor antagonist (subject to contraindications). Optimal agents and their duration are best chosen to balance the reduction of thrombotic and bleeding risks for individual patients.

Thus the agents used in combination with aspirin as part of DAPT may include:

A. ***Thienopyridines (e.g. clopidogrel, prasugrel and ticagrelor)*** [70, 104, 110, 112, 113]: Oral $P2Y_{12}$ inhibitors are commonly used in DAPT, for all ACS patients during admission and for 12 months thereafter. Clopidogrel still has common use but slow onset of action (>6 hours, 3–5 days without dose loading) can be problematic if stent protection is not adequate. Prolonged half-life may increase bleeding if urgent CABG is required. [104] Prasugrel and ticagrelor have rapid and more reliable action, which favours their use in the setting of PCI; patients with high bleeding risk may need exclusion. [70, 104, 112]

B. ***Glycoprotein IIb/IIIa inhibitors (GPIs)*** [2, 6, 28, 70, 77] Abciximab, eptifibatide and tirofiban, developed prior to oral $P2Y_{12}$ inhibitors, were of critical importance during PCI and they still retain a role in complex lesions. Oral GPIs were disappointing with significant increases in bleeding and mortality. The safer profile of $P2Y_{12}$ inhibitors and suitability for long-term oral therapy has seen GPI use decline.

Antithrombotic Therapy and New Agents [2, 28, 112]

Ruptured plaque activates thrombin. Antithrombin therapy is generally given in combination with fibrin-specific fibrinolytic agents. In the setting of primary or early PCI, antithrombin use is mandatory.

Four anticoagulants are currently used clinically (UFH, LMWH, bivalirudin and fondaparinux), in support of thrombolysis, PCI or their combination. Hospitals should have protocols reflecting international guidelines.

Thrombolysis [2,28] with fibrin-specific agents requires anticoagulant therapy for at least 24–48 hours. Weight-adjusted intravenous UFH may be preferred if PCI is likely. Otherwise, LMWHs (e.g. enoxaparin) are preferred as reliable bioavailability removes the need for monitoring activated partial thromboplastin time. Meta-analyses suggest an advantage of enoxaparin to UFH, a lower composite end-point of death, non-fatal MI and cerebral haemorrhage, but with an increase in non-fatal bleeds. [114] Heparin-induced thrombotic thrombocytopaenia syndrome (HITTS) from previous or prolonged UFH can complicate UFH therapy. [82,114–116] LMWHs may need dose adjustment relating to age, body weight and renal function. Fondaparinux (pentasaccharide Factor Xa inhibitor) should not be used with PCI. Guideline recommendations and licencing for use can vary.

Primary PCI [2,28] requires 'heparin' (IV infusion or bolus dosing) prior to commencement. Agents and doses depend upon concurrent antiplatelet therapies (including GPIs), renal function, bleeding risk and stent. Intravenous-loaded enoxaparin is superior to UFH in primary PCI, [28,117,118] but requires dosing adjustment for age and renal function. Bivalirudin (direct antithrombin inhibitor), is an alternative in primary PCI. [28,117] Fondaparinux is not recommended for primary PCI because of a peculiar problem of end-catheter thrombosis. [28,117]

Beta-Blockers [2,28,74,119–122]

Pre-thrombolysis era trials demonstrated major benefits from early beta-blocker therapy (IV and oral), leading to their continued aggressive use. Post-thrombolysis trials of early use have demonstrated less benefit and even harm. [2,44,74,119,121,122] Oral β-blockers should be started in all patients in the first 24 hours, subject to the absence of HF, impending shock, bradycardia, heart block or asthma. [2] In the Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study (COMMIT/CCS-2) early IV β-blocker therapy in MI had lower rates of recurrent MI and VF, but balanced higher rates of cardiogenic shock, especially on days 0 and 1, [2, 119] STEMI patients undergoing primary PCI and without HF (echocardiography assisting) may benefit from cautious IV β-blockade. [123]

Renin-Angiotensin-Aldosterone System (RAAS) Inhibitors [28]

RAAS inhibitors include angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs). Initial ACEI doses may cause hypotension, but early introduction post-STEMI (within the first 48 hours) is generally well tolerated and is associated with a small reduction in 30-day mortality, which is evident in the first week. [28] Early benefits are additive to β-blockade and antiplatelets.

Other Therapies

Nitrates may be beneficial for the treatment of recurrent angina, LVF and hypertension, but may be harmful if hypotension deters proven therapies such as ACEIs or β-blockers. Glucose–insulin–potassium therapies have not been shown to provide ‘cardio-protection’. Hydroxymethylglutaryl-coenzyme-A (HMG-CoA) reductase inhibitors (‘statins’) are recommended for secondary prevention if there are no contraindications.

Complications of Myocardial Infarction

Arrhythmias [8, 28, 122, 124] (See Chapter 31)

Arrhythmia management is discussed in detail in Chapter 31 and in modern international guidelines. [125] Post-MI arrhythmias are minimised by:

- rapid revascularisation and treatment of HF
- correct hypoxia, hypovolaemia and acid-base disturbances

- maintain serum potassium in normal range (3.5–4.5 mmol/L) and magnesium (0.7–1.2 mmol/L).[125,126]

Rhythm disturbance is common during acute MI, especially around onset, and during reperfusion. This can include ventricular ectopy and transient tachyarrhythmias but most do not require intervention. (Ventricular tachycardia may occur in 6% of ACS in the first 48 hours.) There has been a steady decline in the incidence of VF, from approximately 4.5% to less than 2% of MI admissions.[127,128] Early β-blockers reduce the incidence of VF and are generally first-line therapy for the management of ventricular ectopy.[125] *Routine* lignocaine and magnesium have not demonstrated benefit.[8,44,125,129] When ventricular tachyarrhythmias require treatment, amiodarone and lignocaine are preferred to the Class 1 agents.[124] Ventricular arrhythmias and ventricular ectopics beyond 48 hours indicate at-risk patients needing full reassessment and likely electrophysiological studies to determine long-term management.[123,124]

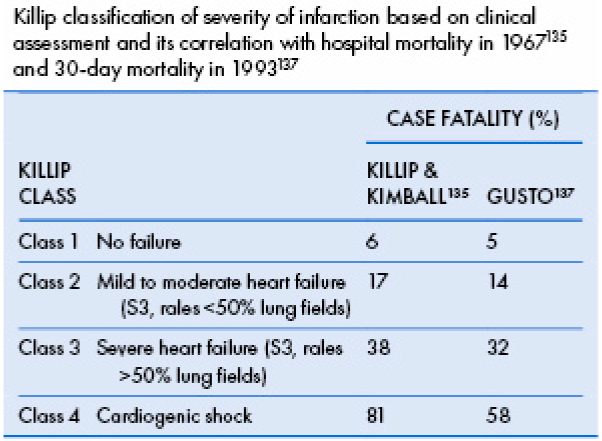
Post-Infarction Angina and Re-infarction[28,36]

Angina (STEMI or NSTEMI) may occur at rest, or with minimal exertion in the 24 hours or more after MI. It is associated with increased mortality, and the re-infarction rate and can complicate MI after thrombolysis or PCI. Ischaemia may occur in the original infarct zone, or in a distant area when there is complex vessel disease. Pathology may include recurrent thrombus or vessel spasm. Tachycardia, hypertension, anaemia and fever should be corrected and aggressive treatment with antiplatelet agents, nitrates and β-blockers is indicated. The patient should be examined, angiography reviewed and repeat angiography reconsidered to exclude vessel (or stent) re-occlusion. Echocardiography will assess LV function and possible mechanical complications. Refractory pain with ECG changes is indicative of high risk and is usually an indication for revascularisation.[2] Insertion of an intra-aortic balloon pump may help improve symptoms and minimise ischaemia, and may bridge further PCI or CABG. Re-infarction in the 10 days following STEMI occurs in up to 5%–10% of patients.

Cardiac Failure (See Chapter 33) and Cardiogenic Shock (Table 29.4) [27, 28, 44, 86, 130–134]

LV dysfunction is the single strongest predictor of STEMI mortality. Heart failure complicating a patient's first ACS hospitalisation ('Index HF') complicates 15% of STEMI and NSTEMI, presence rising to perhaps 25% at 1 year. In-hospital mortality is 15% compared with 3% in STEMI without HF. [134] Rates are higher in patients with previous MI. The Killip Classification documents simple bedside findings (Table 29.5) [28, 131, 135–137] to allow risk evaluation. Scores correlate strongly with LV function and prognosis at the time of hospitalisation.

Table 29.5



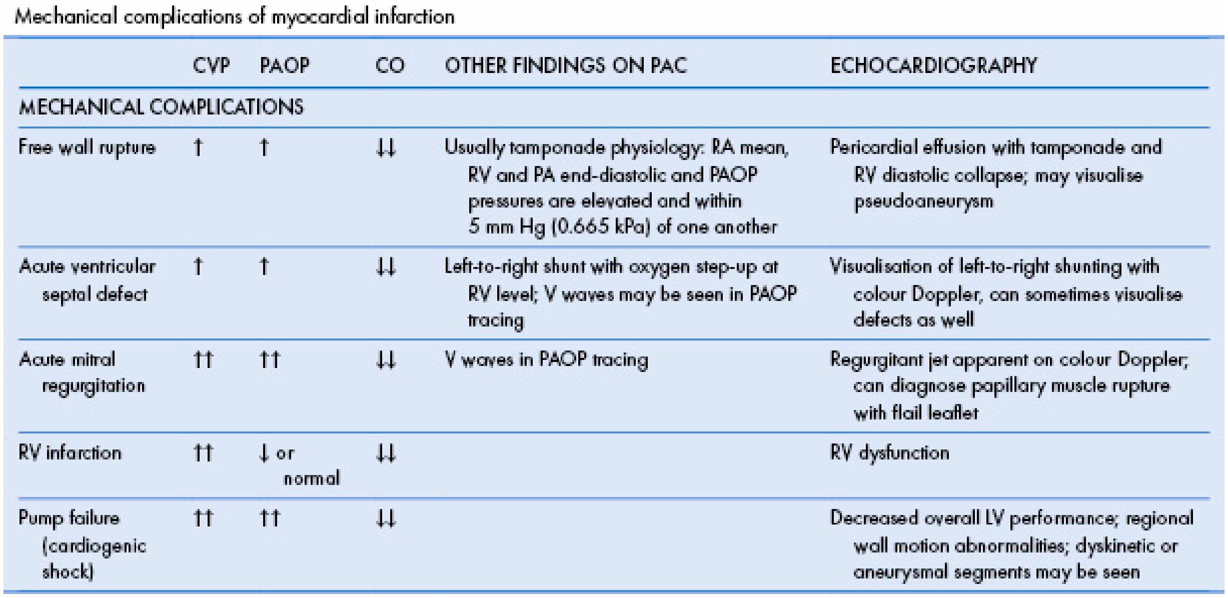
Killip classification of severity of infarction based on clinical assessment and its correlation with hospital mortality in 1967[135] and 30-day mortality in 1993[137]

		CASE FATALITY (%)	
KILLIP CLASS		KILLIP & KIMBALL[135]	GUSTO[137]
Class 1	No failure	6	5
Class 2	Mild to moderate heart failure (S3, rales <50% lung fields)	17	14
Class 3	Severe heart failure (S3, rales >50% lung fields)	38	32
Class 4	Cardiogenic shock	81	58

There is a strong correlation between the degree of left ventricular dysfunction and mortality in acute coronary syndrome.

Reproduced with permission from Thompson P. *Coronary Care Manual* . 2nd ed. Sydney: Churchill Livingstone Australia; 2011.

Table 29.4



Mechanical complications of myocardial infarction

	CVP	PAOP	CO	OTHER FINDINGS ON PAC	ECHOCARDIOGRAPHY
MECHANICAL COMPLICATIONS					
Free wall rupture	↑	↑	↓↓	Usually tamponade physiology: RA mean, RV and PA end-diastolic and PAOP pressures are elevated and within 5 mm Hg (0.665 kPa) of one another	Pericardial effusion with tamponade and RV diastolic collapse; may visualise pseudoaneurysm
Acute ventricular septal defect	↑	↑	↓↓	Left-to-right shunt with oxygen step-up at RV level; V waves may be seen in PAOP tracing	Visualisation of left-to-right shunting with colour Doppler, can sometimes visualise defects as well
Acute mitral regurgitation	↑↑	↑↑	↓↓	V waves in PAOP tracing	Regurgitant jet apparent on colour Doppler; can diagnose papillary muscle rupture with flail leaflet
RV infarction	↑↑	↓ or normal	↓↓		RV dysfunction
Pump failure (cardiogenic shock)	↑↑	↑↑	↓↓		Decreased overall LV performance; regional wall motion abnormalities; dyskinetic or aneurysmal segments may be seen

---

Echocardiography has largely replaced the need for insertion of a pulmonary artery catheter although information for a PAC shown here is useful in understanding physiology. Coronary angiography and studies may be required to determine coronary anatomy and may provide additional data.

CO , Cardiac output; *CVP* , central venous pressure; *PA* , pulmonary artery; *PAC* , pulmonary artery catheterisation; *PAOP* , pulmonary artery occlusion pressure; *RA* , right atrium; *RV* , right ventricle.

Standard treatment for HF should be followed which is covered in greater detail in subsequent chapters. [28, 130]

Right Ventricular Failure

Approximately 50% of patients with inferior STEMIs also have RV infarction, which is associated with higher morbidity and mortality due to the associated arrhythmias and haemodynamic compromise. [138, 139] Proximal occlusion of the right coronary artery causes right RV systolic dysfunction, which is characterised by a stiff and dilated RV, decreased preload resulting in low cardiac output and hypotension.[138] An ischaemic RV is therefore pre-load dependent and reliant on right atrial contraction to enhance RV filling and the LV septum for its contractile function.[139] These patients often require aggressive fluid resuscitation. Compared to the left ventricle, which is susceptible to irreversible necrosis, acute reperfusion of the right coronary artery results in almost complete recovery of RV function.[138,139]

Cardiogenic Shock[2,28,130,132,140–144]

Cardiogenic shock is a state of inadequate tissue perfusion resulting from severe impairment of ventricular pump function in the presence of adequate intravascular volume. It is the leading cause of in-hospital STEMI mortality (35%–50%).[141,142,145] It may complicate 10% of STEMI but also 2%–5% of NSTEMI. Eighty percent of cases result from muscle necrosis and 10%–20% from MI structural disruption.[142] Late presentation or delayed reperfusion are major risk factors[141] and emergency revascularisation with PCI or emergency CABG is critical.[2,28,86,141]

The presence of shock is usually identified by[143,144]:

- SBP less than 90 mm Hg or fall in mean arterial pressure 30 mm Hg below baseline
- cardiac index: less than 1.8 L/min/m^2 despite adequate filling pressures but without vasoactive drugs, or less than 2.0–2.2 L/min/m^2 with support.

Patients with cardiogenic shock or severe HF, or at high risk of these, should be urgently transferred to centres of excellence, regardless of time post-MI.[2,86] Improved outcomes in cardiogenic shock have resulted from primary PCI replacing thrombolysis, from ‘rescue’ of failed thrombolysis, and from PCI in NSTEMI with late-onset shock. Mortality has improved from 70%–80% to 40%–50% due to early revascularisation[146,147] but remains very high (55%–70%) in established cases, however, which is increasingly due to co-morbid illness in ageing populations.[140]

Cardiogenic shock is characterised by the failing of the heart and hypoperfused organs, initiating a vicious cycle of deterioration. Rigorous attention to all organ functions is required.

- ***Reperfusion*** with PCI or CABG should always optimised. Many patients have greater than 75% stenosis of all three coronary arteries including the LAD, and 'stunned myocardium' may recover with revascularisation and support.[86,130]
- ***Respiratory assistance*** should maintain oxygenation, but also minimise cardiac demands of the work of breathing. Whilst early intubation and mechanical ventilation are often undertaken, non-invasive ventilation (CPAP) is vital in both support and ventilator weaning (Chapter 43). Echo may monitor afterload and RV pre-load changes.[148,149]
- ***Haemodynamic management*** seeks to support coronary perfusion, cardiac output and organ perfusion, without increasing myocardial ischaemia.[142,143,150] The need for inotropy, vasodilation, vasoconstriction or their combination may guide therapy, although trial data are often lacking (see also Chapters 73 and 26).
- ***Mechanical cardiac support*** is of major importance and is increasingly recognised as superior to intra-aortic balloon counterpulsation, which lacks evidence of mortality benefit (see Chapter 28). The role of intra-aortic balloon pump (IABP) in cardiogenic shock patients presenting with STEMIs has waned over the years with publication of the SHOCK-II trial in 2012.[151] This was an unblinded randomised control trial of 600 patients who were assigned to either IABP or standard medical care in STEMI patients complicated by cardiogenic shock. The trial showed no reduction in 30-day mortality in the IABP compared to standard care. In addition, IABP also did not show any improvement in ICU length of stay, requirement for renal replacement therapy, requirement or length of mechanical ventilation or dose and duration of catecholamines.[151] Conversely, the use of IABP also did not show any increase in complications such as sepsis. Subsequently, the recommendation of routine use of

IABP in STEMI patients with cardiogenic shock has been downgraded to a Class IIaB indication in the USA and a Class IIbB indication in Europe. [28, 133] However, IABP still plays a role in bridge to cardiac surgery for patients suffering from mechanical complications from myocardial infarctions, including haemodynamic instability secondary to acute mitral regurgitation [152] or for haemodynamic support in patients with high-grade left main stenosis or three vessel coronary artery disease being transferred to a surgical centre. [153]

- ***Other treatments*** include seeking to maintain sinus rhythm or to ‘regularise’ atrial fibrillation, to consider dual chamber pacing where pacing is required, and to consider early renal support. Decision planning should always seek to involve the patient, especially where hospital discharge with good function is unlikely.

Mitral Regurgitation [2, 44, 140, 142, 154]

Transient ‘functional’ MR is common early after MI, as LV wall dysfunction or enlargement may cause subvalvular apparatus displacement and incomplete valve closure. This may be asymptomatic and silent (identified only on echocardiography in 30%). Severe MR and papillary rupture can complicate even small, ‘confined MI’ (50% of cases) but may not have a classical pan-systolic murmur and its presence should be sought with echocardiography in any patients with HF or shock, especially women. Incomplete chordae rupture is better tolerated haemodynamically. Posteromedial leaflet rupture is most frequent as its blood supply arises from a single coronary artery via the posterior descending coronary artery (from the right coronary artery or the circumflex coronary artery, depending upon dominance). The anterior-lateral papillary muscle has a dual blood supply but its single body or head is prone to complete rupture. A decrescendo systolic murmur may be present rather than the typical pan-systolic murmur of chronic MR.

The incidence of catastrophic MR has fallen with the introduction of primary PCI and thrombolytic therapy (1%–5% to <0.5%). It may occur early, often on days 1–4 post-MI. It is usually lethal without surgery.

Chronic MR can be a late complication of MI due to a combination of papillary muscle injury and ventricular remodelling. In the first instance, it is best treated medically.[2]

Cardiac Rupture[2, 19, 28, 155, 156]

The incidence of cardiac rupture has fallen significantly in the PCI era.

- LV-free wall rupture (0.5% of MI) causes tamponade, which is usually catastrophic. Subacute rupture is less common, may mimic re-infarction and have a classic ‘to-and-fro’ flow on echocardiography.
- Interventricular septal rupture has an incidence of 0.2% in the PCI era.[156] Anterior and inferior MI are equally represented and single-vessel disease is not uncommon.[140] Patients usually rapidly develop shock and a loud systolic murmur,[2] although initially the murmur may be soft with fewer symptoms. Echocardiography will help exclude mitral valve rupture. Progressive clinical deterioration is usual (untreated, mortality can be 50% at 1 week, 90% at 1 year) and requires urgent surgery in selected patients despite high mortality.[2] Better survival with later surgery may reflect selection bias. Some cases undergo percutaneous closure, usually as a bridge.[27]

Systemic Emboli[19, 157–162]

Embolic ischaemic stroke was historically common occurring after large anterior MI (20%–55%).[158] Mural LV thrombus was frequent, often large and strokes usually occurred early. The incidence has fallen dramatically due to primary PCI, adjuvant supportive treatments and routine early echocardiography. Ischaemic strokes will occur with an incidence of approximately 2% in-hospital or by day 30, and up to 4% at 1 year. In-hospital mortality of ischaemic stroke can be 10%–20%.[157, 158]

The highest risk of ischaemic stroke is in the first 6 months after MI and guidelines have led to early post-MI ‘prophylactic’ anticoagulation where there is atrial fibrillation, or anterior wall mural thrombus, or the risk factor of decreased LVEF (<40%). Anticoagulation is normally continued long term for atrial fibrillation, and for 3–6 months with echo monitoring of LV mural thrombus cases. Whilst guidelines support an indication for anticoagulation therapy because of impaired LVEF alone and without thrombus, [44] there are concerns that this does not provide benefits because of bleeding mortality. [160, 161] The previous guidelines both provided Class 2B, Level of Evidence: C recommendation for anticoagulation for STEMI patients with LV anterior wall akinesis or dyskinesis. [2, 163, 164] The 2017 European STEMI guidelines, however, do not recommend prophylactic anticoagulation following a STEMI. [26] It is proposed those patients with large LAD territory infarcts and no mural thrombus on contrast TTE performed within 72 hours following PCI can be managed with DAPT. [162] A repeat TTE should be conducted 1–2 weeks post-MI where the risk of LV thrombus formation is the highest. [162]

Post-Myocardial Infarction Injury Syndrome (Dressler's Syndrome) and Pericarditis [165]

A pericardial rub may develop 24–72 hours after large, usually anterior MI. Associated pain may mimic ischaemia, and biomarkers and echocardiography may be useful in excluding post-infarction angina. Dressler's syndrome is a later-presenting pericarditis (2–3 weeks after MI) thought to be an immunopathic response to myocardial necrosis. It is characterised by fever, pleuro pericardial pain and rub, arthralgia and elevated inflammatory markers, and can occasionally be recurrent. Treatment includes NSAIDs and occasionally, steroids. It is now very uncommon (<1%); fewer incidences are perhaps due to improved and earlier reperfusion, leading to smaller MIs. [165]

Management of Unstable Angina and NSTEMI (NSTEACS) [8, 29, 36, 58]

NSTEACS are now far more frequent than STEMI. Pathology is also secondary to platelet aggregation and thrombosis upon an unstable plaque with elements of obstructive ischaemia, vasospasm and mircroembolisation.[36] Much acute adjuvant therapy is similar to STEMI, and secondary prevention is common to most ACS.

General principles of treatment are:

- immediate pharmacological relief of ischaemic symptoms
- immediate introduction of antiplatelet therapy, usually in conjunction with an antithrombin agent, to stabilise plaque white thrombus and prevent complete artery occlusion
- assess benefits of early invasive (PCI and vessel reopening) versus medical therapy.

Diverse causes of NSTEAC and frequent co-morbid disease, have required large trials to determine optimal interventions. Management benefits if the patients are stratified at presentation and after, into 'high-risk', 'intermediate-risk' and 'low-risk' groups. Treatment decisions are clinically enhanced by the use of simple, validated scoring systems correlated with mortality and MACEs. A common system is the TIMI Risk Score for NSTEACS.[59], [166]

Percutaneous Coronary Intervention and Stents [88], [167]

PCI involves coronary artery angiography and balloon dilatation (angioplasty), now usually followed by 'stent' placement. Thrombosis from angioplasty or the presence of coronary stents requires procedural, and often long-term, antiplatelet therapy. Following angioplasty, recurrent stenosis (processes of 'pathological remodelling') was frequent,[88] initiating the development and use of bare metal stents (BMS). Although less frequent with BMS, stenosis ('neointimal inflammatory injury') was problematic (20%–30% of lesions).[88] Newer generation 'drug-eluting stents' have significantly decreased stenotic events, but at least 12 months of DAPT are recommended following ACS and 6 months following PCI for stable ischaemic heart disease.[70,168] Interruption of DAPT for non-cardiac surgery before 3 months may be harmful but may be considered between 3 and 6 months if the risk of delaying surgery outweighs the risk of stent thrombosis.[70,168] The ICU team, in conjunction with other acute care teams, needs an understanding of the risk of procedural and stent complications where adjuvant treatment requires interruption. These can include bleeding from antiplatelet therapy and heparins, stent thrombosis from their withdrawal and vascular access or procedural-related complications, including coronary perforations.

Transradial access via the right radial artery is performed in majority of the cases and is the preferred method of access (Class I indication).[6] Radial access was associated with lower rates of bleeding and all-cause mortality compared to the femoral approach.[169] Radial access complications include perforation (<1%), radial artery occlusions (<1%–33%) and haematomas and compartment syndrome (0.004%).[170] Femoral approach via right femoral artery may be given preference due to operator experience or in the case of cardiogenic shock or graft studies to access the left internal mammary. The risk of significant bleeding with femoral access for coronary angiography is between 1% and 3% and is associated with high blood transfusion rates and hospital length of stay.[171] Retroperitoneal bleeding is life-threatening and should be considered in a haemodynamically unstable patient following femoral access. Other femoral access complications include haematomas, pseudo-aneurysms, closure device failure and limb ischaemia.[172]

The causes of unexpected haemodynamic instability during PCI are numerous. Sudden haemodynamic collapse can be caused by arrhythmias, catheter dampening, coronary perforation, no-reflow or thrombosis, cardiac tamponade, acute aortic or mitral regurgitation or aortic injury.[173] An ICU team responding to an emergency in the cardiac catheter laboratory must have a rapid framework to evaluate these possibilities in collaboration with the interventional cardiologist.

Early Invasive Versus Medical Therapy in NSTEACS[8,36]

Although medical therapy is introduced to all patients, review of ECG, biomarker changes and instability may guide the timing of PCI.

Risk stratification is integral to the management of patients with ACS. Scoring systems based on simple and rapidly available clinical and laboratory tests, help to guide therapy. The GRACE [6, 57] and TIMI [55, 59] risk scores for UA/NSTEMI predict both in-hospital and post-discharge, 6-month mortality. Emergent PCI is demonstrated to offer clinical benefits to patients with high-risk features such as elevated troponins, recurrent chest pain and recurrent ECG changes.

Anti-Ischaemic Agents

Initial therapy with oxygen is started if the patient is hypoxic; reassurance and analgesia are as described for all ACS.

- ***Nitrates sublingual*** may provide immediate symptom improvement, but infusions more effectively provide control of symptoms and ST-segment changes; however, data do not suggest a mortality benefit. [6, 8]
- ***β-blockers*** [8, 174–176] should be started orally within 24 hours in patients without contraindications but with caution. Guideline recommendations are presumed from STEMI data. [8] Risk factors for shock are common in the NSTEMI and STEMI population, and urgent therapy may cause harm in such patients.
- ***Calcium channel blockers*** non-dihydropyridine agents (e.g. diltiazem or verapamil) [8, 36] may provide symptom relief when β-blockers or nitrates are not tolerated, but LVF is a contraindication as cardiogenic shock may be precipitated. [2]

Aspirin and Dual Antiplatelet Therapy [8]

Treatment guidelines for acute, in-hospital use of aspirin and DAPT align closely with those of STEMI. The primary difference is that the European ACS guidelines for 2023 do not recommend pre-treatment with a second antiplatelet therapy for patients with unknown coronary anatomy. [29]

Antithrombins and Anticoagulants [5, 6, 36]

- Heparins are used acutely in NSTEACS to inhibit thrombin production or activity and decrease thrombus complications.[5, 6] The addition of UFH to aspirin therapy produced a significant reduction in recurrent angina and subsequent MI.[36, 177] LMWHs and UFH produced similar results (less difference than in STEMI)[177] but simplicity, a lack of need for monitoring and an acceptable safety profile may favour LMWH use – except perhaps where surgery is anticipated.
- Bivalirudin is an alternate anticoagulant treatment supporting early PCI. Fondaparinux if used during PCI risks end-catheter thrombosis.

Ongoing and Discharge Care of Acute Coronary Syndromes (Secondary Prevention)

Many therapies have been studied in the long-term (secondary) treatment of ACS and have a strong evidence base. These treatments are very similar for STEMI and NSTEACS and may offer mortality and morbidity advantages for other atherothrombotic illnesses:

1. **Antiplatelet therapy** . Aspirin[2, 8, 107, 110, 178] should be continued life-long in all types of ACS and the benefit has been still present at 10 years.[179] Low-dose aspirin (75–150 mg/day) is as effective as higher doses, which show no further benefit but are associated with increased bleeding.[178] DAPT is generally recommended for all ACS patients for 12 months unless contraindicated. Longer duration DAPT, and a change in its nature should be determined on periodic review according to perceived balancing ischaemic and bleeding risks, and in accordance with international guidelines. Patients who discontinue aspirin despite high coronary risk, have a threefold risk of MACE, which is even

higher when stents are in place.[180] Even patients who have been stable after 1 year have a high incidence of future atherothrombotic events[110] and aspirin benefits are still present at 10 years.

2. ***β*** **-blockers** historically have been recommended long term for all patients with ACS. Patients with impaired LV function (LVEF <40%) should continue long-term therapy. In asymptomatic patients with good LV function, guideline confidence levels supporting life-long therapy have fallen, perhaps due to the improvements from PCI, DAPT and angiotensin-converting enzyme (ACE) inhibitors.[121,175,181]
3. ***Inhibitors of RAAS*** *(see Chapter 33):* Patients with anterior MI, and LVEF less than 40%, maintained on long-term ACE inhibitors may experience a sustained 20% RRR in mortality (additive to benefits of aspirin and β-blockers), and a significant reduction in the incidence of LVF.[4,28]
4. ***Lipid-lowering agents***[2,182–184] : ACS patients should commence an HMG-CoA reductase inhibitor [‘statin’] on the first day after admission.[185–187] Early decreases in major adverse cardiac events may be due to plaque stabilisation rather than regression of stenoses. All ACS patients should continue long-term ‘statin’ therapy, with mortality benefits being seen at 1 year. Statins reduce both vascular events and mortality, in primary and secondary settings, and benefits apply to both men and women.[183] Intensive statin therapy is superior to less-intensive lipid reduction (lower all-cause mortality)[188,189] and each 1.0 mmol/L reduction in LDL cholesterol may reduce major cardiovascular events (RRR) by 20%, major coronary events by 25%, need for coronary revascularisation by 25% and ischaemic stroke by just under 20%.[183]

   Although statins are associated with a small risk of incidental Type 2 diabetes, this is outweighed by the reduced all-cause mortality. Proprotein convertase subtilisin kexin 9 (PCSK9) inhibitors (i.e. evolocumab and alirocumab) have been shown to be effective in reducing cholesterol and LDL-C levels. Whilst these monoclonal antibodies shown to improve cardiovascular outcomes, they have had little effect on mortality. [4, 190, 191]

5. ***Other anti-ischaemia agents*** **:** Calcium channel blockers are of symptomatic use in patients intolerant of β-blockers or where there is a clinical need such as hypertension or arrhythmia but do not decrease recurrent MI or mortality. [4, 28]
6. ***Antiarrhythmic therapy:*** Arrhythmias are discussed in Chapter 31 and in recent international guidelines. [125]
7. **Anticoagulants** [2, 28, 29, 161, 192] : Long-term anticoagulation is generally only indicated for specific indications, including atrial fibrillation, LV mural thrombus, history of embolic events, prosthetic heart valves or a prothrombotic tendency and some with severe LV dysfunction. Increased use of DAPT has necessitated a review of INR targets, especially in the elderly. New oral anticoagulants (NOACs) have increasingly replaced warfarin, a trend which is likely to continue as reversal agents improve safety. [192] For patients who require anticoagulation (i.e. atrial fibrillation) following an ACS, the default strategy should be triple therapy (Aspirin, Clopidogrel and a NOAC) for 1 month followed by dual therapy with Clopidogrel and a NOAC for up to 12 months followed by a NOAC alone thereafter. Clopidogrel is the antiplatelet of choice when combined with a NOAC. Ticagrelor and prasugrel should be avoided due to higher bleeding risks. A shorter duration of dual therapy could be considered in patients with high bleeding risk or low ischaemic risk. [193, 194]
8. **Lifestyle advice:** All patients should be compliant with medication, cease smoking and receive advice on exercise and diet. [96] Tight control of blood pressure and blood sugar in diabetics is of high importance. [195] Regular medication review and confirmation of compliance are useful. A Cochrane meta-analysis found that exercise-based cardiac rehabilitation may be associated with improved outcomes. [196]

Myocardial Infarction in the Intensive Care Unit [47, 167, 197–201]

MI is a common reason for admission to the ICU, often to facilitate acute management or to treat associated organ dysfunction. In patients managed acutely with STEMI or NSTEMI, primary PCI is the general treatment. Where possible, recognised guidelines should be applied.[2, 6, 28, 29, 77, 85] However, critically ill patients are often not enrolled in clinical trials and co-morbid conditions in NSTEMI and STEMI admissions vary the risk-benefit of usual treatments. They often require continuous integrated team assessments, with further investigation and treatment on a case-by-case basis.

A difficulty in the management of ‘general’ ICU patients, is that cTN may be elevated in up to 40%–50%, including those with diagnoses of sepsis, pulmonary embolus and non-cardiac surgery (see Chapter 33 and Box 29.1). A presumption of ischaemic pathology (‘oxygen mismatch’), would define these as Type 2 MI.[7, 201] However, clinical evidence of ischaemia (voiced chest pain, ECG changes and RWMA) is often absent (perhaps in only 20% of cases) and they may now be considered ‘myocardial injury’ or MINOCA.[7, 62, 200, 201] MINOCA is an increasingly recognised entity and such would require further investigation. Irrespective of the presence of ischaemic features, they are associated with increased early and later mortality that may often be ‘non-cardiac’.[198–200] It is uncertain as to how treatment guidelines apply to such patients and how much cardiological follow-up is required. Carroll[47] indicates the value of patient team review and management with input of data from echocardiography and possible angiography. The known value of antiplatelet therapies in ACS suggests they should be introduced where possible with the support of stents following PCI on a risk-benefit judgement.

The need and nature of pre-operative investigation of high-risk surgical patients are also difficult. Studies of major, non-cardiac surgery[198] found greater than 12% of patients had an elevated cTn level by post-op day 3. Mortality was 1% in patients with normal cTn but ranged from 4% to 16%, at day 30 in groups of patients in accordance with their day-3 elevation. Again, death causation was often ‘non-cardiac’. Although only 50% of deaths were thought to be ‘vascular’, vascular investigation would seem appropriate to reduce mortality. Pre-operative exercise testing can identify patients with early positive tests, but it is unclear if revascularisation of low-risk disease patients will improve their outcomes if stent insertion requires perioperative interruption and then long-term continuation of antiplatelet therapy. Trials of peri-operative beta-blockade, statin therapy or antiplatelet agents have often not shown any benefit.[202,203] Meta-analyses of statin therapy prior to CABG have not demonstrated any benefit.[204]

Takotsubo Syndrome [39,40,205–209]

Takotsubo cardiomyopathy presents with acute, reversible LV dysfunction, usually with chest pain, dyspnoea or syncope causing it to mimic an ACS (2% of such cases). Physical, pharmacological or emotional stresses may trigger 70% of cases. Up to 90% of cases occur in postmenopausal women and such cases may make up to 10% of this female demographic presenting with an initial ACS diagnosis. In up to one-third of patients no triggers are identified.[210] Biomarker or ECG changes (30% may have STE) generally necessitate coronary angiography to exclude MI, although by definition plaque rupture is absent.[39,40,207,209]

Echocardiography[46] reveals classical apical ‘ballooning’, with preserved basal contraction (the ‘takotsubo’ or ‘Japanese octopus pot’ appearance) which occurs in 75%–80% of the cases.[211] This appearance results from a hypercontractile base of the heart with LV outflow tract obstruction, relative to a hypokinetic or akinetic apical and mid-LV ballooning myocardium; variants include a ‘reverse takotsubo’ appearance, with mid-cavity or basal ballooning which occurs in 10%–20% of patients.[211,212] The physiology of Takotsubo cardiomyopathy is uncertain, but ‘high levels of epinephrine’ may paradoxically trigger cardiodepression due to increased LV afterload, coronary vasospasm and microvascular dysfunction,[209,213] which is most marked in apical regions because of a β_2-receptor gradient with high apical levels decreasing along the LV wall to the base.[40,208]

Major complications in severe Takotsubo cardiomyopathy include hypotension, HF, cardiogenic shock, arrhythmias, LV thrombus and MR.[39] Acute mortality can be 2.4%–4.5% and co-morbid illnesses are often the primary cause of death.[205, 207] Annualised recurrence may be up to 1.5%.[207] Most cases of Takotsubo cardiomyopathy improve with supportive treatment.[39, 208] Echocardiography can help diagnose and assess response to therapy, and fluids should be administered to avoid hypovolaemia. In the presence of hypotension and shock, ideal inotropic therapy has not been defined. In severe shock, early mechanical support is often indicated as a ‘bridge-to-recovery’.[39, 208]

Septic Cardiomyopathy [214–216]

In the same spectrum as reversible cardiac dysfunction, septic cardiomyopathy (SCM) is a condition that is increasingly recognised in intensive care units. SCM is defined as sepsis-induced acute transient myocardial dysfunction that may affect the systolic or diastolic function of the LV and/or RV.[216, 217] The pathophysiology underlying SCM has not been elucidated. Several postulated mechanisms include myocardial ischaemia caused by microvascular dysfunction, mitochondrial dysfunction and exposure of cardiomyocytes to chemical mediators including endotoxins, cytokines and nitric oxide.[214, 215, 218]

Echocardiography is the imaging modality of choice for diagnosing septic cardiomyopathy.[216] However, the difficulty lies in distinguishing SCM from other conditions, such as HF, myocarditis and ACS, which may also manifest with acute cardiac dysfunction and elevated troponin levels.[219] SCM is typically diagnosed in the absence of ACS or other cardiomyopathies. A history of HF, on the other hand, does not rule out the possibility of SCM. The recovery of cardiac function upon resolution of sepsis is indicative of the presence of SCM.

Bleeding Complications and Acute Coronary Syndromes Therapies [168, 192, 220–222]

Hospital protocols and a multidisciplinary team response with skilled laboratories are required to plan major surgery and reverse major bleeding.[5, 6, 26, 28, 168, 220, 223] Treatment protocols for UFH, vitamin K antagonists and aspirin-related bleeding are generally known to clinicians.

1. **Antiplatelet agents and DAPT**[104, 168]: Antiplatelet drugs have no specific reversal agents. In uncontrolled bleeding, platelets are administered and additional treatments may include DDAVP (desmopressin) and recombinant Factor VIIa (rFVIIa). The $P2Y_{12}$ oral medications have no specific 'antidotes' and treatment with these agents is also useful in this setting. The GPI abciximab can be associated with early thrombocytopaenia in 5% of patients, responsive to platelet transfusion and usually settling within a week. Tirofiban and eptifibatide have very short half-lives when renal function is normal, and antiplatelet action returns to normal 4–8 hours after discontinuation. Whilst platelets are given, their effect is uncertain and with critical bleeding in vivo studies suggest that fresh frozen plasma (8 units) and platelets (2 units) may help reverse antiplatelet action.[223] However, as ticagrelor is a reversible P2Y12 inhibitor, the effects of platelet inhibition have been shown to be reversed by 50% after two platelet transfusions 24 hours after the initial ticagrelor dose.[224, 225]
2. ***Antithrombins***[221]: UFH has historically been treated with dose-related protamine. Protamine treatment of LMWH is variable and incomplete, reversing perhaps only 60% of the LMWH with recommended doses. Protamine reverses 100% of the anti-IIa activity but has far less effect on anti-Xa activity. With ongoing bleeding, rFVIIa is considered. Danaparoid, a heparinoid, is sometimes required in patients with HITTS. Its high anti-Xa/anti-IIa activity ratio168 of 20 renders it less likely to respond to protamine, and treatments have included plasmapheresis and high-dose rFVIIa. Fondaparinux has no specific antidote, but rFVIIa has been administered in severe bleeding.
3. ***Direct oral anticoagulants (DOACs)***[220, 222]: These directly inhibit the coagulation cascade with a long-term safer profile than

warfarin, but reversal of active bleeding has been extremely difficult. Dabigatran (a thrombin, Factor IIa binder) may be fully reversed by the monoclonal antibody idarucizumab, having been poorly responsive to cryoprecipitate, prothrombinex and rFVIIa.[192] Factor Xa inhibitors, rivaroxaban and apixaban, can now be reversed with andexanet, if available.[192]

4. ***Thrombolytic agents*** : Published studies for life-threatening bleeding have suggested large doses of cryoprecipitate (10–20 units), repletion of fibrinogen and coagulation factors (especially Factor VIII). Fresh frozen plasma may supplement Factor V and VIII whilst platelet transfusions at high doses may replace platelets and supplement Factor V levels. ε -aminocaproic acid, loaded, followed by infusion has been suggested. Tranexamic acid might be useful.[220] Thrombolytic reversal carries the risk of culprit coronary artery re-occlusion.[223] Whilst publications may advise general advice, individual clinical scenarios and varying and multiple agents suggest considerable caution with overriding on-site multi-specialty input.

Outcome After Myocardial Infarction

In-hospital mortality from MI has been steadily decreasing over the past three decades, from 15% to 30% in the 1970s to approximately 10% in 1980, and now to around 7%–9% in the new millennium.[1, 3–6, 226] Thirty-seven percent of the reduction of in-hospital mortality for STEMI and 21% of that for NSTEMI have been attributed to improvements in acute treatment.[1] Furthermore, 30-day mortality adjusted for age and sex improved from 10.5% in 1999 to 7.8% in 2008.[227] This was primarily driven by a decrease in case fatality rates in the NSTEMI population whilst there was no significant change over time for STEMIs.[227] Despite improved mortality, 60% of all deaths occur within the first hour (usually from VF) and often before reaching a medical facility.[5, 6, 84] Modern management of MI has undoubtedly contributed to decreased mortality. Further significant reductions in mortality must come from management strategies within the first hours of the onset of symptoms.

The most effective strategies to improve outcomes are [1, 4, 28, 226]:

- systems to deal with out-of-hospital VF arrest
- strategies to increase rates, and reduce time delays of PCI or thrombolysis in eligible patients
- optimise prescription and compliance with adjuvant and discharge medications.

Missed opportunities for reperfusion are a major problem. In one study, in-hospital mortality was 5.7% for those who received thrombolysis, but 14.8% for eligible patients who did not receive thrombolysis (mortality 9.3% vs. 18% in eligible women; 10.5% vs. 19% in eligible elderly). Up to 24% of eligible patients may not receive reperfusion therapy.[78, 84, 226, 228] The role of early reperfusion and the provision of reperfusion therapy for all eligible persons, with ongoing life-long adjunctive management, cannot be underestimated.

Cardiopulmonary resuscitation (including defibrillation)

Peter Thomas Morley and Jerry P. Nolan

Over the past two decades, there have been improvements in cardiac arrest outcomes in both the in-hospital and out-of-hospital settings. [1], [2] There are many potential reasons for these improvements, but the most likely are related to incremental improvements in the management during and after the arrest. [3] The last decade has also seen the completion of many randomised controlled trials on a variety of interventions at each point in the chain of survival.

Prevalence, Aetiology and Outcomes of Cardiac Arrests

The global incidence of emergency medical services (EMS)-treated out-of-hospital cardiac arrest (OHCA) is in the range of 30–100/100,000 person-years. [4] In 2019, in Australia and New Zealand, the incidence of EMS-treated OHCA was approximately 40/100,000 person-years. [5]

The incidence of in-hospital cardiac arrest (IHCA) with a resuscitation attempt is in the range of 1–10/1000 admissions. [6]

The majority of OHCAs are of primary cardiac cause, but the causes, co-morbidities and presenting rhythms vary significantly between studies. Furthermore, the pre-hospital diagnosis is often incorrect. Among 314 OHCAs treated in Adelaide, 84% were considered pre-hospital to be of cardiac cause, yet after investigations in-hospital the final precipitating cause was identified as cardiac in 53%, respiratory 18%, toxicological 6%, neurological 3%, other 9%, and unknown 11%. [7] A systematic review of IHCAs also documented a spread of aetiology amongst 27,000 cardiac arrests: hypoxia 26%; acute coronary syndrome 18%, arrhythmias 15%, hypovolemia 15%, infection 14% and heart failure 13%. [8]

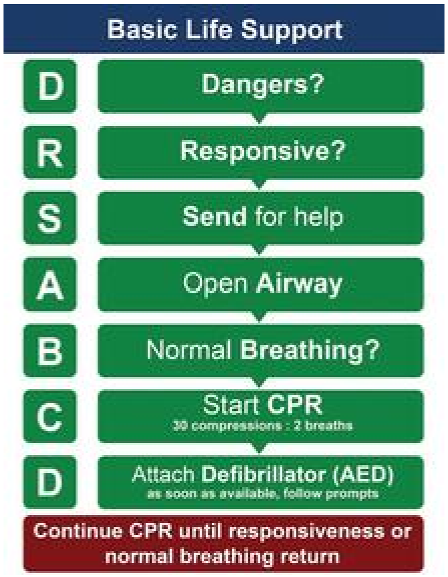
Following EMS-treated OHCA, rates of survival to hospital discharge or 30 days vary internationally but are in the range of approximately 5%–16%. [4] The survival rate in Australia and New Zealand is 12%–16%. [5] The outcomes from IHCA internationally vary but are in the range of 20%–35% for survival to hospital discharge or 30 days. [6]

International Review Process

The International Liaison Committee on Resuscitation (ILCOR) was formed in 1992. It has facilitated a cooperative international evaluation of the resuscitation science, which resulted in the publication of international guidelines in 2000, and international consensus documents on resuscitation science every 5 years since 2005. [9] Since 2015 the process for evidence evaluation has become continuous with summary papers published annually. The Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology is used for systematic reviews (completed reviews available at www.ilcor.org). The major resuscitation councils throughout the world (including the American Heart Association (https://cpr.heart.org/en/resuscitation-science/cpr-and-ecc-guidelines), and the European Resuscitation Council (https://cprguidelines.eu)) use this information as the basis for the development of their published guidelines. The Australasian guidelines (co-badged by the Australian Resuscitation Council and the New Zealand Resuscitation Council) are updated as required, and the current version is published online under the auspices of the Australian and New Zealand Committee on Resuscitation (ANZCOR: www.anzcor.org).

Basic Life Support

The general flow of basic life support (BLS) management is outlined in the updated Basic Life Support flow chart of ANZCOR (Fig. 30.1).



Basic Life Support
D
Dangers?
R
Responsive?
S
Send for help
A
Open Airway
B
Normal Breathing?
C
Start CPR
30 compressions : 2 breaths
D
Attach Defibrillator (AED)
as soon as available, follow prompts
Continue CPR until responsiveness or normal breathing return

The vertical flowchart labelled Basic Life Support is structured into sequential steps marked by initials D, R, S, A, B, C, and D. The first step D represents determining if there are Dangers. The second step R represents determining if the patient is Responsive. The third step S represents to Send for help if there are dangers and the patient is not responsive. The fourth step A represents Open Airway. The fifth step B represents checking that the patient has Normal Breathing. The sixth step C represents Start C P R, which includes 30 compressions to 2 breaths. The final step D represents to Attach the Defibrillator with A E D as soon as available and following prompts. An instruction to continue C P R until responsiveness or normal breathing returns is present at the bottom of the chart.

FIG. 30.1 Basic life support flow chart. (Reproduced with permission from the Australian Resuscitation Council [www.anzcor.org]).

Commencement of cardiopulmonary resuscitation

The current BLS guidelines recommend that cardiopulmonary resuscitation (CPR) be commenced with compressions if the victim is unresponsive and not breathing normally. An appropriately trained advanced life support (ALS) provider can check for a central pulse (e.g. carotid) for up to 10 seconds during this period of assessment, but this should not delay CPR.

External Cardiac Compression

The delivery of high-quality CPR is believed to be a key contributor to the best possible outcomes after cardiac arrest. Several quality factors have been proposed but the best data are for chest compression rate and depth. [10]

Site of Compression

The desired compression point for CPR in adults remains over the lower half of the sternum. Compressions higher than this become less effective, and compressions lower than this are also less effective and have an additional risk of damage to intra-abdominal organs.

Rate of Compression

The optimal rate of chest compressions during cardiac arrest in adults is uncertain, but the international consensus recommendation is for a rate of 100–120/min. [11]

Depth of Compression

The optimal depth of chest compressions is uncertain. The recommended compression depth for adults is 5–6 cm. [11] To achieve this goal, ANZCOR recommends that the chest should be compressed approximately one-third of its depth (in adults, children and infants). Compressions that are too shallow are inefficient and associated with worse outcomes, and compressions that are too deep may be associated with an increase in complications. [12]

Minimise Interruptions to Compressions

Interruptions to chest compressions are common, can be prolonged, and result in a decrease in coronary perfusion pressure and reduced defibrillation success.[13] These adverse effects commence within 10 seconds of stopping CPR but appear to be at least partially reversible with the recommencement of chest compressions. The frequency and duration of interruptions in compressions for rhythm recognition or specific interventions (such as ventilations, charging the defibrillator, defibrillation or placement of devices/equipment) should be kept to a minimum.

Compression:Ventilation Ratio

During CPR the cardiac output is reduced to approximately one-third of normal. The minute ventilation requirements are similarly decreased. A single compression:ventilation ratio of 30:2 remains recommended for adult BLS before the airway is secured (irrespective of the number of rescuers). The tidal breath should be delivered within 1 second, and the desired tidal volume to be delivered is one that results in a visible chest rise.

Monitoring the Quality of Cardiopulmonary Resuscitation

Simple techniques to monitor the quality of CPR include observation of the rate, depth and positioning of chest compressions, the rate and depth of ventilation and palpation of central pulses. Waveform capnography should be considered for all arrests (Box 30.1). Additional monitoring of CPR quality (depth and rate of compressions and ventilation) can be achieved using modified defibrillator pads, or pucks that are placed on the sternum. Real-time feedback from these devices is associated with small improvements in CPR quality but this has not been translated into improved survival,[14-16] even when supplemented with post-arrest debriefing.[16]

Box 30.1

Utility of end-tidal carbon dioxide monitoring during cardiac arrest

Cardiovascular (absolute value of $ETCO_2$)

Falls immediately at the onset of cardiac arrest
Increases immediately with chest compressions
Provides a linear correlation with cardiac index
Allows early detection of ROSC (sudden increase)

Respiratory ($ETCO_2$ waveform)

Allows assessment of tracheal tube placement
Allows assessment of expiratory flow limitation

Prognosis (absolute value of $ETCO_2$)

Predicts successful resuscitation

$ETCO_2$, End-tidal carbon dioxide; *ROSC*, return of spontaneous circulation.

‘Compression-Only’ Cardiopulmonary Resuscitation

Increasing anxiety about the performance of mouth-to-mouth ventilation, greatly exacerbated by the COVID-19 pandemic, [17] has required the consideration of an alternative approach to traditional bystander CPR. Several animal and human studies have suggested that ventilation may not be necessary during the initial phase of resuscitation from an arrest of a cardiac cause. Despite the limited data to support ‘compression-only’ CPR, it is recommended that if there is a high risk of infectious respiratory disease, or if rescuers are unable, not trained, or unwilling to perform mouth-to-mouth ventilation (rescue breathing) then they should perform ‘compression-only’ CPR. The combination of chest compressions and ventilation during cardiac arrest generates large quantities of aerosol. [18]

CPR While Wearing Personal Protective Equipment

The wearing of personal protective equipment (PPE) is essential in many circumstances. There is a lack of clinical studies to assess the impact of PPE, but early published data suggests that the use of PPE was not associated with a reduction of CPR quality or cardiac arrest survival. [19]

Defibrillation

Defibrillation remains the definitive treatment for shockable rhythms, such as pulseless ventricular tachycardia or VF. Most modern defibrillators deliver biphasic waveforms, which are now well established as a safe and effective waveform for defibrillation. Biphasic defibrillators compensate for the wide variations in transthoracic impedance by electronically adjusting the waveform magnitude and duration to ensure optimal current delivery to the myocardium (impedance compensation). [20] The initial shock is usually 150–200 J (depending on the defibrillator). If the first shock is not successful and the defibrillator is capable of delivering shocks of higher energy it is reasonable to increase the energy for subsequent shocks. If the rescuer is unaware of the recommended energy settings of the defibrillator, for an adult use the highest energy setting for all shocks. [20]

Manual Defibrillation or Automated External Defibrillator

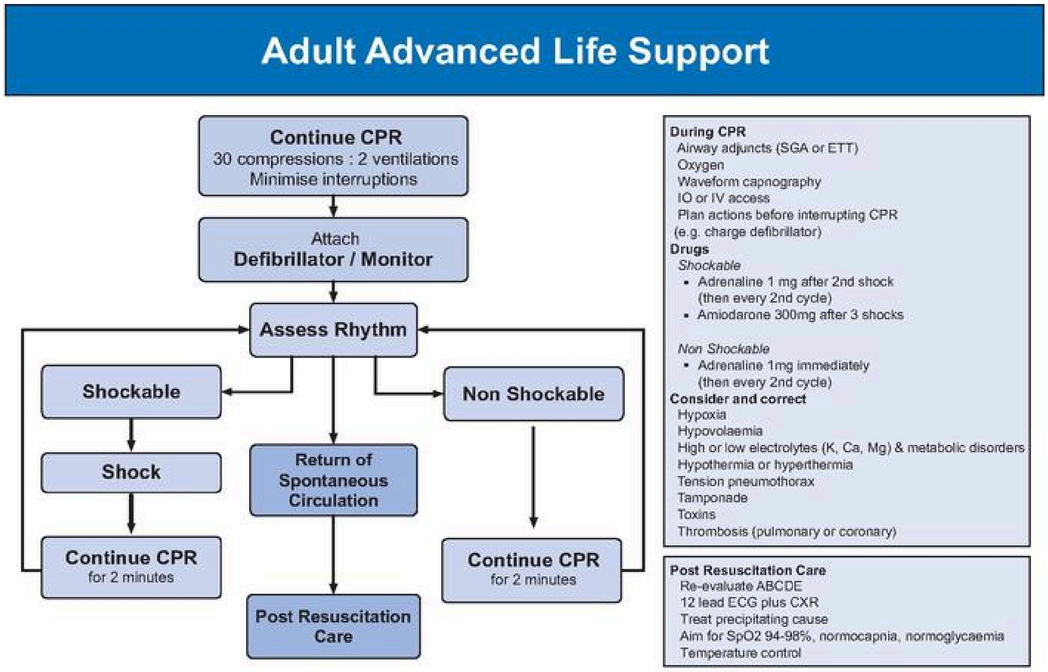
Automated external defibrillators (AEDs) provide an opportunity for BLS providers and untrained bystanders to defibrillate a shockable rhythm. Skilled health care providers should use manual defibrillation whenever possible to avoid the delays inherent in the use of an AED. [21]

Double Sequential External Defibrillation (DSED) and Vector Change

In DSED two defibrillators (pads in anterior-lateral and anterior-posterior (AP) positions) are used to deliver sequential shocks (a second shock is delivered immediately after the first shock, not simultaneously). In vector change (VC), the pads are reorientated to an AP position. In a cluster randomised trial DSED or VC defibrillation was compared with standard defibrillation for refractory VF in OHCA. [22] Survival to hospital discharge and termination of VF were improved with both DSED and VC compared with standard defibrillation. In refractory VF (not responding to three shocks) VC defibrillation has been suggested in the guidelines [20] but if two defibrillators are available it may be reasonable to use DSED.

Advanced life support

ALS has an established role in the management of cardiac arrests, although these interventions have a modest incremental impact on survival compared with early bystander CPR and defibrillation. The recommended sequence of treatment to be followed is outlined in the current ERC guidelines (https://cprguidelines.eu), and the ANZCOR Advanced Life Support flow chart (Fig. 30.2). These flow charts have been designed to be used as both an aide memoire and a teaching tool.



Adult Advanced Life Support
Continue CPR
30 compressions : 2 ventilations
Minimise interruptions
Attach
Defibrillator / Monitor
Assess Rhythm
Shockable
Non Shockable
Shock
Return of Spontaneous Circulation
Continue CPR
for 2 minutes
Continue CPR
for 2 minutes
Post Resuscitation Care

During CPR
Airway adjuncts (SGA or ETT)
Oxygen
Waveform capnography
IO or IV access
Plan actions before interrupting CPR
(e.g. charge defibrillator)

Drugs
Shockable
- Adrenaline 1 mg after 2nd shock (then every 2nd cycle)
- Amiodarone 300mg after 3 shocks

Non Shockable
- Adrenaline 1mg immediately (then every 2nd cycle)

Consider and correct
Hypoxia
Hypovolaemia
High or low electrolytes (K, Ca, Mg) & metabolic disorders
Hypothermia or hyperthermia
Tension pneumothorax
Tamponade
Toxins
Thrombosis (pulmonary or coronary)

Post Resuscitation Care
Re-evaluate ABCDE
12 lead ECG plus CXR
Treat precipitating cause
Aim for SpO2 94-98%, normocapnia, normoglycaemia
Temperature control

The flowchart presents details for advanced cardiopulmonary resuscitation beginning with a top box labelled Continue C P R, specifying 30 compressions to 2 ventilations with minimal interruptions. This leads to the next step labelled Attach Defibrillator or Monitor. From there, the path continues to a step labelled Assess Rhythm. Two branches emerge from this step, one labelled Shockable and the other labelled Non-Shockable. If the rhythm is shockable, the next step is administering Shock, followed by Continued C P R for 2 minutes, which loops back to Assess Rhythm. If the rhythm is non-shockable, the flow proceeds directly to Continue C P R for 2 minutes, which also loops back to Assess Rhythm. From the centre, a separate path leads downward from Assess Rhythm to Return of Spontaneous Circulation, followed by Post Resuscitation Care. A list of instructions is stated on the right. The steps to be taken during C P R are adjunctive measures, including airway support, oxygen, waveform capnography, intraosseous or intravenous access, and planning actions before pausing compressions. Drug guidelines are divided by rhythm type. For shockable rhythms, adrenaline, one milligram, is given after the second shock and every second cycle thereafter, and amiodarone 300 milligrams after three shocks. For non-shockable rhythms, adrenaline, one milligram, is given immediately and every second cycle. The things to consider and correct are reversible causes, including hypoxia, hypovolemia, electrolyte or metabolic disturbances, hypo- or hyperthermia, tension pneumothorax, tamponade, toxins, and thrombosis. Post Resuscitation Care lists steps including re-evaluating A B C D E, obtaining a twelve-lead electrocardiogram with chest X-ray, treating the cause, aiming for oxygen saturation between 94 and 98 percent, normocapnia, normoglycemia, and controlling temperature.

FIG. 30.2 Advanced life support flow chart. (Reproduced with permission from the Australian Resuscitation Council [www.anzcor.org]).

Precordial thump

The provision of a precordial thump may be considered in a monitored arrest due to pulseless ventricular tachycardia if a defibrillator is not immediately available. The technique is not without risks and should not delay defibrillation.

Chest compressions

The provision of good BLS is an essential part of the ALS management of both shockable and non-shockable rhythms. Interruptions to chest compressions for definitive procedures or interventions (such as defibrillation) should be kept to a minimum. Recommence CPR immediately following defibrillation (without checking the rhythm) and continue for at least 2 minutes unless signs of life return (the victim becomes responsive or starts breathing). Even if defibrillation has successfully reverted the rhythm into one that could generate a pulse, in most cases this is not initially associated with an output. Immediate compressions in these situations avoid the detrimental effects of prolonged interruptions in compressions and maintain coronary perfusion. After each 2 minutes of CPR (or if signs of life return), check the underlying rhythm. If a rhythm compatible with return of spontaneous circulation (ROSC) is observed at that time, feel for a central pulse.

Airway Management During Cardiopulmonary Resuscitation

The optimum airway management strategy during CPR is uncertain but randomised controlled trials have shown no benefit for tracheal intubation overuse of bag-mask ventilation [23] or a supraglottic airway [24] during OHCA. A third randomised controlled trial (RCT) showed a higher 72-hour survival with a supraglottic airway (SGA) compared with tracheal intubation. [25] During CPR, start with basic airway techniques and advance stepwise according to the individual rescuer's skills, until effective ventilation is achieved. [20] In instances where an advanced airway (tracheal intubation or a SGA) is required, only those rescuers who have a high success rate (over 95% within two attempts) with tracheal intubation should perform this procedure. Interruptions in chest compressions for tracheal intubation should be kept to less than 5 seconds; in many cases, tracheal intubation can be achieved without any interruption in chest compressions. Use direct or video laryngoscopy for tracheal intubation according to local protocols and rescuer experience. Use waveform capnography to exclude unrecognised oesophageal intubation and use the highest feasible inspired oxygen during CPR.

During ventilation, each breath should be given over a duration of one second, sufficient to achieve a visible chest rise. After the successful insertion of a tracheal tube or an SGA, ventilate the lungs at a rate of 10 per minute and continue chest compressions without pausing during ventilations. If gas leakage occurs when using an SGA and results in inadequate ventilation, pause compressions momentarily for ventilation and continue with a compression-ventilation ratio of 30:2. High respiratory rates during cardiac arrest are associated with increased intrathoracic pressure, decreased coronary and cerebral perfusion, and, at least in animals, a decreased rate of ROSC. [26] If there is a concern about potential gas trapping, a period of disconnection from the ventilation circuit may be beneficial.

Identification of Reversible Causes

Irrespective of the initial rhythm, cardiac arrests can be precipitated or perpetuated by several conditions that if not detected and corrected may decrease the likelihood of successful resuscitation. [27] These ‘reversible causes’ are categorised in the ERC (https://cprguidelines.eu) and ANZCOR ALS algorithms as the ‘4Hs and 4Ts’ (see Fig. 30.2). Several techniques are available to assist in the diagnosis and exclusion of these conditions. These include a good history, a careful clinical examination and some specific investigations and interventions. Echocardiography can potentially diagnose (or help exclude) several cardiac and non-cardiac reversible causes (Box 30.2) but prolonged interruptions to chest compressions must be avoided. [28] Several studies have evaluated the use of transesophageal echocardiography during CPR; this enables continuous assessment during chest compressions and minimises pauses for pulse checks.

Box 30.2

Potentially useful diagnoses detectable by echocardiography

Hypovolaemia [a]
Tamponade [a] (pericardial)
Tension pneumothorax [a]
Thrombosis – pulmonary [a] (thromboembolism)
Thrombosis – coronary [a] (regional or global wall motion abnormalities, including lack of cardiac motion)
Pacemaker capture
Unexpected VF
Acute valvular insufficiency (e.g. papillary muscle rupture)
Ventricular rupture
Aortic dissection
Massive pleural effusion

[a] Reversible causes listed in the '4Hs and 4Ts' (www.anzcor.org) (see Fig. 30.2).

VF , Ventricular fibrillation.

Medications During Cardiopulmonary Resuscitation

Although several drugs have been recommended for use during the management of cardiac arrests, there is only limited evidence for their benefit. Consider the intraosseous route (humeral or proximal tibial) for the administration of drugs and fluids if venous access is not immediately available. [29]

Vasopressors

The putative beneficial effect of vasopressors during cardiac arrest is to increase the perfusion pressure to the heart and brain. [30] The use of intravenous adrenaline in an RCT enrolling out-of-hospital cardiac arrests increased survival to hospital discharge but not favourable functional outcome. [31] The effects of adrenaline on outcomes are greater for patients with an initially non-shockable rhythm than those with shockable rhythms. [32] Given these data, it is considered reasonable to continue to use epinephrine routinely in the management of cardiac arrests. The initial adult dose is 1 mg and this should be repeated approximately every 3–5 minutes. Vasopressin is an alternative drug, but studies have been unable to demonstrate any consistent benefits with its use and it is no longer included in resuscitation guidelines.

Anti-arrhythmics

Administration of amiodarone or lidocaine for shock refractory VF has been associated with increased survival in hospitals when compared with a placebo.[33] In the largest RCT of anti-arrhythmic drugs, neither amiodarone nor lidocaine improved long-term survival when compared with placebo across the board,[34] though there was an increase in survival to discharge with amiodarone or lidocaine compared with placebo in the pre-specified subgroup of patients with a bystander-witnessed arrest.[35] A large observation study comparing the effectiveness of amiodarone and lidocaine for VF/VT IHCA documents higher rates of survival to discharge and favourable functional outcomes with lidocaine.[36] Either amiodarone or lidocaine (but not both) should be considered in those patients still in VF after three shocks.

Other medications

Other medications that should be considered during cardiac arrest are those that address the detected underlying contributing factors. These include electrolytes (such as magnesium or potassium), atropine, sodium bicarbonate and other specific ‘antidotes’ (Table 30.1).[37], [38] Although current guidelines do not recommend the routine use of calcium in cardiac arrest,[20] it is used in about 25% of IHCAs in the United States.[39] In an RCT comparing calcium chloride with saline the primary outcome, ROSC, occurred in 19% of patients in the calcium group compared with 27% in the saline group (risk ratio (RR) 0.72, 95% CI 0.49–1.03; $P = .09$).[40] Although just short of statistical significance, these findings suggest that calcium should not be given to unselected patients in cardiac arrest. Guidelines continue to recommend calcium for cardiac arrest associated with hyperkalaemia.[41]

Table 30.1

Cardiac arrest medications in specific circumstances

MEDICATION	POTENTIAL INDICATIONS
Atropine	Cholinergic/cardiac glycoside toxicity
Antivenom	Snake, funnel-web spider, box jellyfish venom
Benzodiazepines	Sympathomimetic toxicity
Calcium	Hypocalcaemia, hypermagnesaemia, hyperkalaemia, beta-blocker/calcium channel blocker toxicity
Digoxin-specific antibodies	Cardiac glycoside toxicity
Flumazenil	Benzodiazepine toxicity
Epinephrine (adrenaline)	Beta-blocker/calcium channel blocker toxicity
Glucagon	Beta-blocker/calcium channel blocker toxicity
High-dose insulin/dextrose	Beta-blocker/calcium channel blocker toxicity
Lipid emulsion	Local anaesthetic drugs
Magnesium	Hypomagnesaemia, hypokalaemia, hypercalcaemia, tricyclic antidepressant/cardiac glycoside toxicity, torsade de pointes
Naloxone	Opioid toxicity
Potassium	Hypokalaemia
Pyridoxine	Isoniazid toxicity

MEDICATION	POTENTIAL INDICATIONS
Sodium bicarbonate	Hyperkalaemia, tricyclic antidepressant/sodium-channel-blocker toxicity

Reproduced with permission from Smith SW. Drugs and pharmaceuticals: management of intoxication and antidotes. *EXS* . 2010;100:397-460.

The combination of vasopressin with glucocorticoids may have some benefits for in-hospital cardiac arrests. [42] , [43]

Adjuncts to Cardiopulmonary Resuscitation

Many technologies and techniques have been evaluated as adjuncts or alternatives to CPR, but none has been consistently associated with improved outcomes. Mechanical CPR devices have been studied in great detail, but large RCTs have not been able to demonstrate any survival benefit with either the Lund University Cardiopulmonary Assist System (LUCAS) or AutoPulse. [44-46] The combination of active-compression decompression CPR with an impedance threshold device was associated with improved neurological survival in an RCT in out-of-hospital cardiac arrests. [47]

Mechanical devices (such as the LUCAS or the AutoPulse) may be useful alternatives to manual CPR in situations where traditional CPR is difficult or hazardous, for example during transport; during interventions (such as percutaneous coronary interventions [PCIs]); or as a bridge to extracorporeal techniques.

An intervention bundle of head-up CPR in combination with the impedance threshold device and active-compression CPR has been shown to increase cerebral perfusion pressure. [48] Although observational data have shown an association with increased survival, [49] prospective RCTs are awaited.

Extracorporeal cardiopulmonary resuscitation (eCPR)

Some patients in cardiac arrest and who do not respond to initial treatment may benefit from being placed on veno-arterial extracorporeal membrane oxygenation (VA-ECMO) so that oxygenated blood can be circulated to the vital organs thus buying time for a reversible cause of the cardiac arrest to be identified and treated and a spontaneous circulation restored.[50],[51] Observational data suggest a survival rate for this intervention, known as extracorporeal cardiopulmonary resuscitation (eCPR), of about 30%.[50] Three recent RCTs of ECPR in OHCA have produced conflicting results. Two of these RCTs were terminated prematurely after pre-determined interim analyses; one because of the superiority of eCPR[52] and the other because of its futility.[53] A third RCT showed no benefit for eCPR compared with standard ALS.[54] A systematic review of RCTs and propensity-matched studies concluded that compared with conventional CPR, eCPR reduced in-hospital mortality and improved long-term neurological outcomes and post-arrest survival, particularly in patients with IHCA.[55] The most recent treatment recommendation made by ILCOR suggested that eCPR may be considered as a rescue therapy for selected patients with OHCA when conventional CPR is failing to restore spontaneous circulation in settings where this can be implemented (costr.ilcor.org).

Post-resuscitation care

Survival after cardiac arrest is largely dependent on the initial hypoxic-ischaemic insults to the heart and brain (during the no-flow and low-flow periods), the subsequent reperfusion injury after ROSC, as well as any co-morbidities.[56] However, survival is also influenced by subsequent complications, including secondary insults, the ensuing systemic inflammatory response[57] and differences in post-resuscitation care (Box 30.3).[58]

Box 30.3

Key factors to consider after resuscitation from cardiac arrest

Immediate tasks

Re-evaluate Airway Breathing Circulation Disability Exposure (ABCDE)
12-lead electrocardiogram (ECG)
Treat precipitating causes
Re-evaluate oxygenation and ventilation
Temperature control (avoid fever)

Early goals

Continue respiratory support
Maintain cerebral perfusion
Treat and prevent cardiac arrhythmias
Determine and treat the cause of the arrest

Specific tasks

Maintain haemodynamics (SBP >100 mm Hg [13 kPa])
Maintain adequate oxygenation (SaO_2 94%–98%)
Maintain normal pH and normocarbia (e.g. $PaCO_2$ 35–40 mm Hg [4.5–5.2 kPa])
Treat hyperglycaemia (>10 mmol/L), but avoid hypoglycaemia
Temperature control to prevent fever
Maintain appropriate sedation
Treat seizures
Continue search to identify underlying cause(s) and trauma related to resuscitation
Consider specific treatment for underlying cause (e.g. percutaneous coronary intervention and thrombolytics)

Consider transfer to cardiac arrest centre

SBP , Systolic blood pressure.

Cardiac Arrest Centres

A European consensus statement on the aims, function and structure of cardiac arrest centres [59] and a recent narrative review [60] provide greater detail on this topic. Observational data document increased survival among OHCA patients transported to a hospital that is equipped to provide all components of post-arrest care (including early coronary angiography, temperature control and multimodal prognostication) compared with transport to the nearest hospital. [61] Treatment of post-arrest patients in high-volume centres is also associated with better outcomes. [62] However, these are data that are subject to bias and in a recent RCT, expedited transfer to a cardiac arrest centre for non-ST-elevation OHCA did not reduce mortality in comparison with transfer to the nearest available emergency department. [63]

Temperature Control

Two RCTs from 2002, [64], [65] supported by extensive pre-clinical data, [66] showed an improvement in survival among comatose OHCA patients treated with mild hypothermia (33–34°C) for up to 24 hours. Two more recent and methodologically more robust clinical trials failed to show any difference in outcome among cardiac arrest patients cooled to 33°C versus 36°C [67] and versus fever control (≤ 37.7°C) [68] respectively.

ANZCOR currently suggests actively preventing fever by targeting a temperature less than or equal to 37.5°C for patients who remain comatose after ROSC from cardiac arrest. Whether certain subpopulations of cardiac arrest patients may benefit from lower (32–34°C) or higher (36°C) temperatures remains unknown. Although a recent trial showed no difference in outcome among post-cardiac arrest patients treated with normothermic temperature control for 36 hours compared with 72 hours, [69] current recommendations are to prevent fever for 72 hours in comatose post-cardiac arrest patients. [70]

Additional Factors in Post-Resuscitation Care

Attention should be given to good supportive care for the patient after cardiac arrest. This includes maintenance of cerebral perfusion, provision of adequate oxygenation, ventilation, glucose control and treatment of seizures. [71]

Oxygenation

Excessive cellular oxygen concentrations at the time of reperfusion may increase tissue injury partly because of the generation of highly reactive oxygen free radicals. Pre-clinical studies and observational data from intensive care registries have documented an association between hyperoxaemia and worse outcomes after cardiac arrest but these findings are inconsistent across all studies and are highly subject to bias. [72] An individual-level patient data meta-analysis of randomised controlled trials concluded that conservative oxygen therapy was associated with reduced mortality at the longest follow-up after cardiac arrest. [73] In contrast, a clinical trial that randomised comatose OHCA survivors receiving intensive care to oxygen targets of 68 to 75 mm Hg (9–10 kPa) compared with 98 to 105 mm Hg (13–14 kPa) showed no difference in mortality or functional outcome. [74] Titration of oxygen immediately after ROSC in the pre-hospital setting is challenging. In the rEduction of oXygen After Cardiac arrest Trial (EXACT) haemodynamically stable OHCA patients were randomised to a target SpO_2 of 90%–94% or 98%–100%. [75] Survival to hospital discharge was lower in the group with a target SpO_2 of 90%–94% ($P = .047$) and this group also had more hypoxaemic episodes. These findings suggest that early titration of oxygen to a SpO_2 target of 90% to 94% should be avoided, particularly in the pre-hospital setting where SpO_2 is the only available measurement and titration of oxygen is limited. It is reasonable to titrate to normoxaemia in hospital when blood oxygen saturation can be monitored continuously and reliably.

Ventilation

Numerous studies in animals and humans have demonstrated the potential harm of cerebral ischaemia induced by hypocapnia after cardiac arrest. A small phase II trial suggested that mild hypercapnia among OHCA survivors may be beneficial, [76] but a recent large RCT showed no difference in outcome between 24 hours of mild hypercapnia (50–55 mm Hg) and normocapnia (35–45 mm Hg). [77] Given these data, it seems reasonable to aim for normocapnia in comatose post-cardiac arrest patients.

Blood Pressure Control

The optimal blood pressure after ROSC is uncertain. Some observational data show an association between higher mean arterial blood pressure and better outcomes among comatose post-cardiac arrest patients but such studies are highly biased. A randomised clinical trial (BOX) compared two mean arterial pressure (MAP) targets (63 mm Hg and 77 mm Hg) in 789 comatose post-cardiac arrest patients. [78] The clinicians were blinded because the internal calibration of the invasive blood pressure monitors was adjusted by ±10%. There was no difference in the composite outcome of death or poor functional outcome at 90 days. An individual patient data meta-analysis of 4 RCTs (including the BOX trial) concluded that targeting a higher MAP compared to a lower MAP is unlikely to reduce mortality or improve neurologic recovery after cardiac arrest. [79] It is likely that optimal blood pressure will vary among patients and it seems reasonable to individualise MAP targets.

The Sedation, Temperature and Pressure after Cardiac Arrest Resuscitation (STEPCARE) trial is currently recruiting a target of 3500 patients in a 2×2×2 randomised format to receive a targeted arterial pressure >85 mm Hg or >65 mm Hg, deep or minimal sedation, and fever management with or without a feedback device (NCT05564754).

Glucose Control

Despite the early promise of improved outcomes with tight blood glucose control, subsequent studies have demonstrated this approach to be potentially harmful. Blood glucose should be monitored frequently after cardiac arrest. Hyperglycaemia (>10 mmol/L) should be treated with insulin, and hypoglycaemia should be avoided.

Percutaneous Coronary Intervention

Patients with OHCA have a high prevalence of coronary artery disease. [80] Urgent coronary angiography and percutaneous coronary intervention (PCI) if indicated should be undertaken in post-arrest patients with ST elevation or a new left-bundle branch block, irrespective of the neurological state. However, several RCTs have shown no benefit for urgent coronary angiography in post-cardiac arrest patients without ST elevation on their ECG. [81] These studies excluded patients with haemodynamic instability and such patients should be considered for urgent angiography even in the absence of ST elevation. [71]

Treatment of Seizures

Seizures are common after cardiac arrest (about one-third) and most of these are myoclonic seizures. [82] They may be refractory to multiple medications and although it is reasonable to institute prompt and aggressive treatment of seizures, there is no definitive evidence to suggest that this approach (or preventative therapy) improves outcomes. In a recent RCT, the treatment with anti-seizure drugs of rhythmic and periodic electroencephalographic (EEG) patterns did not improve neurological outcomes in comparison with standard care. [83]

Computed Tomography

Early CT scanning is being adopted increasingly as a standard of care in comatose post-cardiac arrest patients. It may enable diagnosis of the cause of cardiac arrest (e.g. pulmonary embolism) or identification of complications of CPR (rib fractures occur in 70% of resuscitated OHCA patients). [84] Evolving technology may enable CT coronary angiography to be used to exclude coronary artery disease. [85] The pan-CT scan (head, cervical spine, pulmonary angiography, abdomen and pelvis) is likely to be increasingly adopted in much the same way as it is used after major trauma.[86]

Prognostication

It is impossible to accurately predict the likely extent of neurological recovery either during or soon after a cardiac arrest. In patients who remain comatose after cardiac arrest the prediction of likely outcome is important so that organ support is not continued indefinitely in those with no chance of a favourable outcome whilst, conversely, preventing withdrawal of life-sustaining therapy (WLST) in those who have the possibility of a favourable outcome. Current guidelines emphasise a multimodal approach to prognostication (clinical examination, imaging, electrophysiological tests and biomarkers).[87] Any consideration of WLST following the prediction of a poor outcome should generally not be considered until at least 72 hours after cardiac arrest and only after the exclusion of confounders such as residual sedation. Most studies have focused on the prediction of poor outcomes, but prediction of good outcomes also has value, particularly in informing discussions with relatives.[88]

Organ Donation After Cardiac Arrest

The gift of organ donation can be offered to the families and carers of those post-cardiac arrest patients who do not survive: this topic is covered in more detail in Chapter 115 “Organ Donation” . The issues raised are also addressed in the ILCOR scientific statement on organ donation after OHCA.[89]

Arrests in Special Circumstances

Cardiac arrests can occur in a myriad of contexts, and we continue to learn how tailoring our approaches to the individual may be beneficial. A full discussion of special circumstances is beyond the scope of this chapter, but they are covered by published guidelines (www.anzcor.org).[41] Consensus-based guidelines exist for cardiac arrest after cardiac surgery[90] and cardiac arrests in the cardiac catheter lab.[91]

Maintenance of ALS Skills

ALS training is associated with improved patient outcomes.[92] Many studies have confirmed that the knowledge and skills related to ALS start to deteriorate relatively quickly after completion of ALS training (e.g. within 6 months).[93] It is recommended that ALS training includes human factors and team training, and additional simulations or education may be necessary at more frequent intervals to ensure all staff maintain their skills.[94]

Summary

Improved outcomes over the past decade are almost certainly due to a number of incremental improvements in the management of patients during and after cardiac arrests. The key to continual improvement lies with techniques to improve early delivery of good-quality BLS, as well as attention to detail in the post-resuscitation care phase and accurate prognostication. We are awaiting the publication of a number of exciting studies, and hopefully, their results will inform further improvements in survival over the next decade.

Cardiac arrhythmias

Andrew Holt and Russell David Laver

Cardiac Electrophysiology

The electrophysiological properties of cardiac cells are important in understanding cardiac arrhythmias and their management. Cardiac cells undergo cyclical depolarisation and repolarisation to form an action potential (AP). The shape and duration of each AP are determined by the activity of ion channel protein complexes creating electrochemical gradients across the myocyte surface (Table 31.1).[1]

Table 31.1

AV , Atrioventricular; *SA* , sinoatrial.

Ion channels are large glycoproteins that span the membrane bilayer with accessory subunits that contribute to pore structure or modulate function. The genes encoding all the major ion channels have been cloned and sequenced.

Channel activation forms pores that permit rapid transit of ions, creating ionic currents that determine the magnitude and rate of change of myocyte membrane potential.

Ion Channels Have Two Important Properties

[2]

- **Ion Permeability**

Channels are classified based on selectivity for Na^+, K^+ and Ca^{++}. Selectivity is determined by ion size (including ionic hydration) and valency. Most channels have rectifying properties whereby they conduct ions more effectively in one direction.

- **Gating** – is the mechanism by which channels open and close.

Most are voltage gated and modulated by ligand binding.

Voltage-gated channels change their conductance in response to change in membrane potential. Majority of channels open in response to depolarisation, whereas pacemaker channel I_f opens in response to hyperpolarisation.

Ligand-gated channels include $I_{K\ Ach}$, the muscarinic-gated K^+ current where binding of acetylcholine mediates vagal effect by decreasing diastolic depolarisation in sinoatrial (SA) and atrioventricular (AV) pacemaker cells. $I_{K\ ATP}$ channels bind ADP activating phase 1 and 2 K^+ current to shorten the AP matching force generation and duration to cellular energy or ADP levels. This effect is also arrhythmogenic due to a shortened refractory period. The $I_{K\ ATP}$ channel is a target to break the link between ischaemia and arrhythmia. The cardioprotective effect of $I_{K\ ATP}$ plays a role in ischaemia preconditioning.

Mechanosensitive or stretch-activated channels alter AP in response to beat-to-beat variations in pressure and volume. With increases in load, SA node pacemaker rate is increased, whereas the refractory period and conduction are reduced. Sustained pressure and volume load are arrhythmogenic via these changes to the AP.

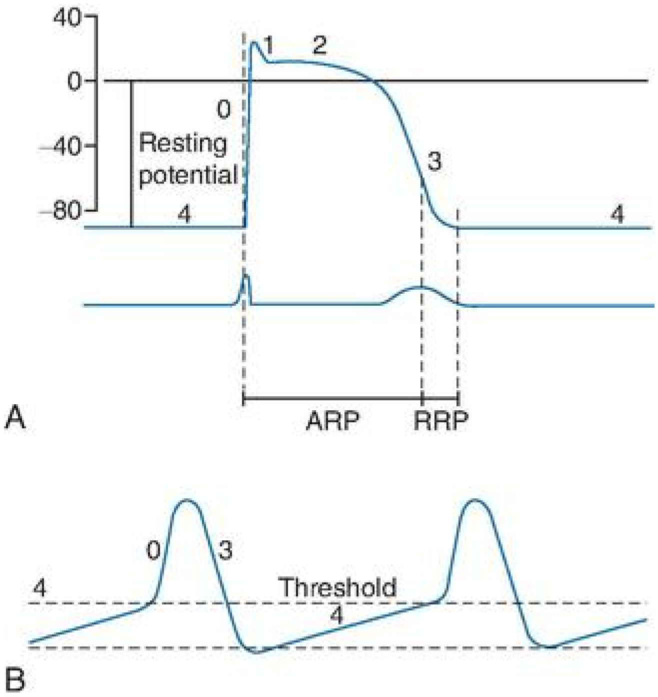
Many of the ion channels are the molecular targets for antiarrhythmic drugs. The differential distribution of ion channel populations within the heart allows drugs to have preferential activity on different parts of the heart.

I_f ‘pacemaker’ channels are confined to the SA node and drugs with specific I_f-blocking activity such as ivabradine have been shown to be beneficial in angina and heart failure by slowing the heart rate without negative effects on ventricular contractility.

I_K channels responsible for potassium ion (K^+) repolarisation currents (I_K) vary throughout the heart with the rapidly activating forms, I_{Kur}, being confined to the atrium. Vernakalant, a new K-channel blocker has predominant activity on the I_{Kur} channel and therefore predominant atrial activity.

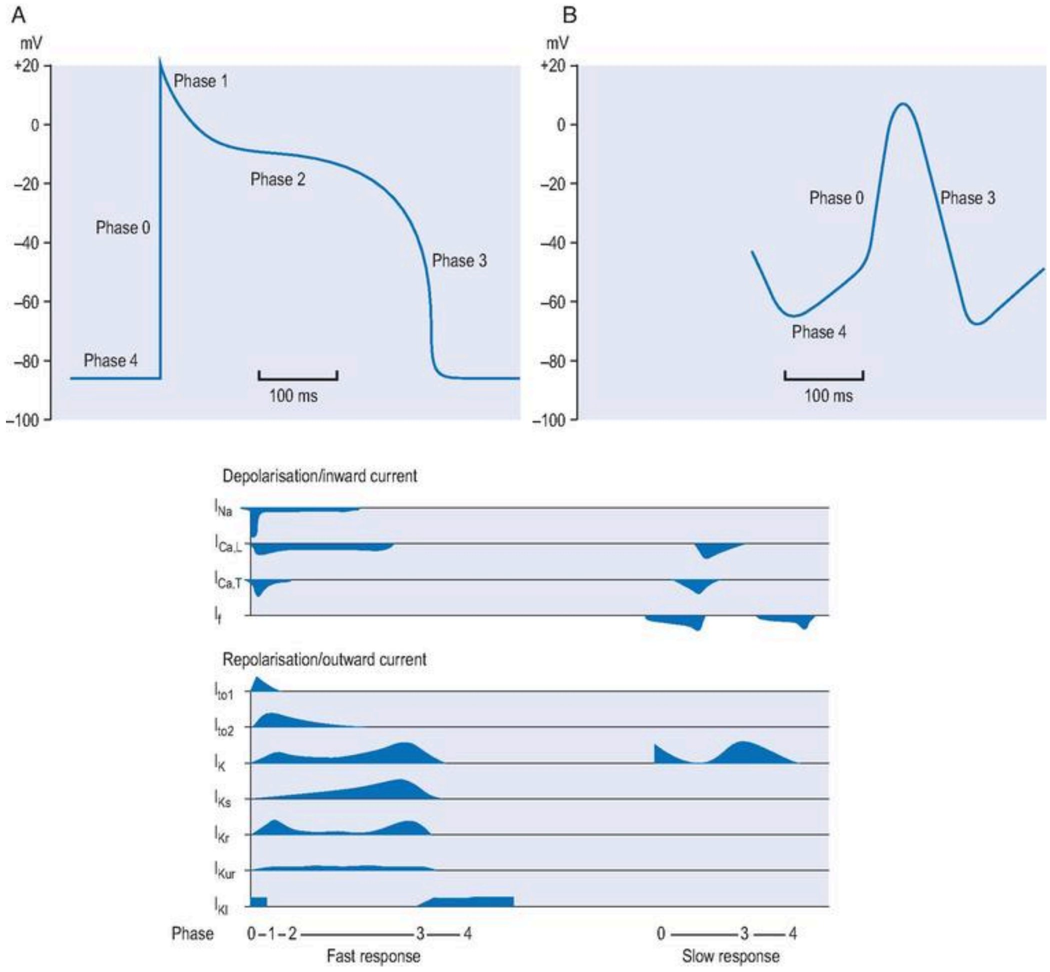
• Cardiac Action Potential

The spectrum of cardiac APs varies from *fast-response* cells – conducting and contractile myocytes (Fig. 31.1A) – to *slow-response* cells of pacemaker myocytes – SA and AV nodes (Fig. 31.1B). Fast myocytes lose their characteristic AP and behave more like slow myocytes when ischaemic. The AP is divided into five phases and ion channel currents vary between fast- and slow-response cells (Fig. 31.2).



The two labelled diagrams, labelled A and B, illustrate cardiac action potentials. Part A shows a line graph of membrane potential over time with five phases labelled 0 to 4. Phase 0 indicates a sharp rise, phase 1 a brief drop, phase 2 a plateau, phase 3 a fall to negative potential, and phase 4 a return to resting potential. The absolute refractory period spans from phase 0 to early phase 3, and the relative refractory period spans late phase 3. Part B presents two action potentials labelled with phases 0, 3, and 4, with a threshold line and sequential electrical activity.

FIG. 31.1 (A) Action potential in a fast-response, non-pacemaker myocyte: phases 0–4, resting membrane potential – 80 mV, absolute refractory period (ARP) and relative refractory period (RRP). (B) Action potential in a slow-response, pacemaker myocyte. The spontaneous upward slope of phase 4, on reaching threshold potential, results in an action potential.



The two graphs labelled A and B, and the two current flow diagrams, represent cardiac action potentials. Part A presents a graph labelled fast response, with membrane potential on the vertical axis and time on the horizontal axis. It includes phases 0 to 4. Phase 0 shows a steep upward spike, phase 1 a brief dip, phase 2 a plateau, phase 3 a decline, and phase 4 a return to baseline. Part B presents a graph labelled slow response, which shows a more gradual change through phases 0, 3, and 4. Below, two horizontal bar diagrams depict ionic current activity by phase. The top diagram represents depolarization or inward currents with five labelled channels, which include I N a, I C a T, I C a L, I f, and I N a C a. The lower diagram represents repolarization or outward currents across ten labelled channels, which include I to, I K r, I K s, I K 1, I N a K, I C l, I K p, I C l C a, and I C l is. The width of each blue shape indicates the current magnitude during each phase across fast and slow responses.

FIG. 31.2 Temporal relationship between action potential and ionic channel activation for: (A) fast-response ventricular myocytes and (B) slow-response pacemaker myocytes.

Phase 0

In fast myocytes (see Fig. 31.1A), rapid depolarisation I_{Na} current occurs owing to activation of voltage-gated sodium ion (Na^+) channels. Activation is initiated in an all-or-none response once the threshold is reached. The Na^+ channels are then inactivated as membrane potential rises to +30 mV and remain inactivated until repolarisation occurs. Rapidity of depolarisation determines speed of conduction. In slow-response myocytes, depolarisation does not involve Na^+ channels and the slower rate of depolarisation is due to a slow inward calcium ion (Ca^{2+}) current via $I_{Ca\text{-}L}$ and $I_{Ca\text{-}T}$ voltage-dependent Ca^{2+} channels.

Phase 1

Early rapid incomplete repolarisation to approximately 0 mV occurs owing to activation of transient outward current from I_{TO1} and I_{TO2} K^+ channels. Slow myocytes do not exhibit phase 1 or 2 characteristics (Fig. 31.1B).

Phase 2

The prolonged plateau repolarisation of fast myocytes is a consequence of low membrane conductance to all ions. The decreasing inward Ca^{2+} current of $I_{Ca\text{-}L}$ and $I_{Ca\text{-}T}$ Ca^{2+} channels is initially balanced and then overcome by the outward K^{+} current of the delayed rectifiers or the I_{k} family of K^{+} channels. During this phase, the rise in calcium ion concentration ($[Ca^{2+}]_{i}$) is the trigger to release sarcoplasmic reticulum stores of Ca^{2+} and initiates the contractile process.

Phase 3

Relatively rapid repolarisation occurs as outward K^{+} current of the delayed rectifiers increases. The I_{kr} K^{+} channel, one of the I_{k} delayed rectifiers, is the common mechanism whereby antiarrhythmic drugs (Class III) prolong the AP and refractoriness.

Phase 4

This is a stable electrical state in fast non-pacemaker myocytes owing to inward rectifier I_{K1} channels maintaining resting membrane potential (RMP) near K^{+} equilibrium and the absence of I_{f} pacemaker channels. In slow pacemaker myocytes, phase 3 I_{KI} current repolarises membrane potential activating I_{f} channels. Subsequent pacemaker depolarisation of phase 4 to threshold occurs due to I_{K1} channel closure and I_{f} depolarising current (Fig. 31.1B).

Fast-response and slow-response myocytes also have important differences in properties of refractoriness. In fast myocytes, Na^{+} channels are progressively reactivated during phase 3 repolarisation as the membrane potential becomes more negative. When an extra stimulus occurs during phase 3, the magnitude of the resulting inward Na^{+} current and the likelihood of impulse propagation depend on the number of reactivated Na^{+} channels. Refractoriness is therefore determined by the voltage-dependent recovery of Na^{+} channels. The absolute refractory period (Fig. 31.1) is the minimum time needed for recovery of sufficient Na^{+} channels for a stimulus to result in impulse propagation. However, once propagation in fast myocytes occurs, conduction velocity is normal. In contrast, slow-response or Ca^{2+} channel-dependent myocytes exhibit time-dependent refractoriness. Even after full repolarisation, further time is needed before all Ca^{2+} channels are reactivated. Stimuli during this period produce reduced Ca^{2+} current and the propagation velocity of any resulting impulse is reduced. The conduction velocity independence of premature APs with fast-response myocytes is lost in the setting of Na^{+} channel-blocking drugs or ischaemia because they behave increasingly like slow-response myocytes with resulting slowed impulse conduction.

Genetic basis to arrhythmia [3]

In the absence of structural abnormalities of the heart, primary electrical disease is associated with mutations in ion channel genes. The long-QT syndrome (LQTS) (see later), short-QT syndrome, Brugada syndrome (idiopathic ventricular fibrillation, VF), catecholaminergic polymorphic ventricular tachycardia (VT) and all causes of sudden cardiac death (SCD) in the young are examples of primary electrical disease where genetic mutations encoding for ion channel proteins have been characterised.

Inheritable forms of structural ventricular disease are associated with atrial arrhythmias and SCD. Examples include hypertrophic and dilated cardiomyopathies and arrhythmogenic right ventricular dysplasia, which are linked to mutations in sarcomeric, cytoskeletal and intercellular junction proteins, respectively.

The risk of cardiac arrhythmias and SCD in the setting of acquired structural heart disease such as ischaemic heart disease is in part genetically determined. Studies demonstrate an increased risk of SCD in patients who have a parental history of cardiac arrest.

Molecular Basis to Arrhythmia [3]

Structural and electrical remodelling in response to myocardial injury, altered haemodynamic loads and changes in neurohumoral signalling lead to alterations in:

- ion channel function
- intracellular calcium handling
- intercellular communication
- composition of intercellular matrix.

All of these factors lead to heterogeneous slowing of conduction velocity and prolonged refractoriness.

Tachycardia remodelling of the atrium is associated with:

- reduced functional expression of L-type Ca^{2+} channels, intracellular Ca^{2+} overload and shortening AP duration.

Heart failure is associated with:

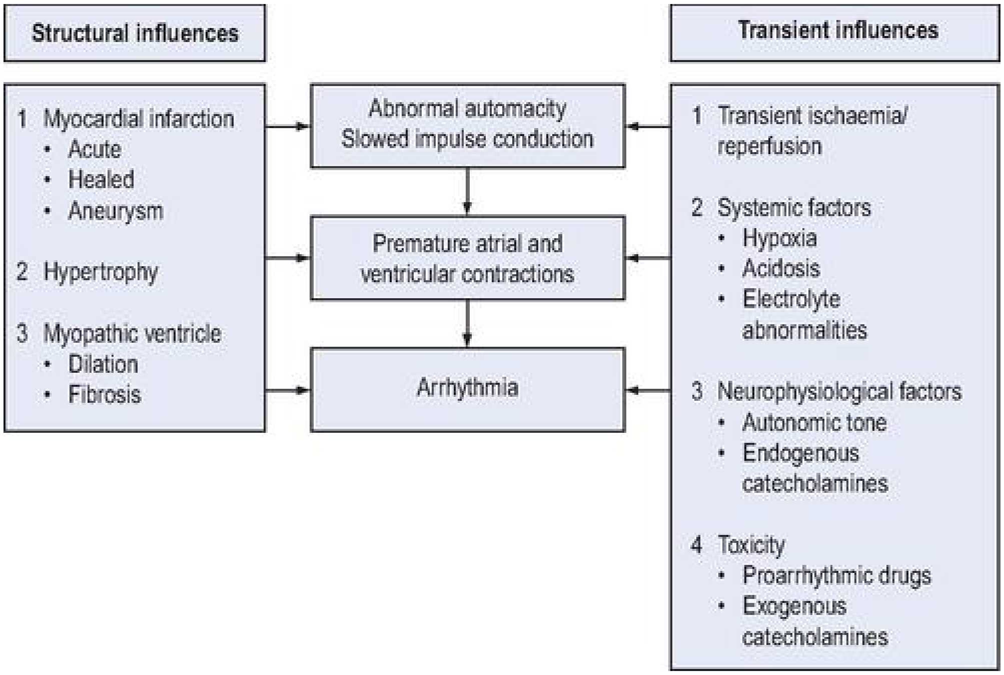
- downregulation of each of the major repolarising K^{+} currents, prolonging repolarisation and resulting in susceptibility to early-after-depolarisation (EAD)-mediated arrhythmia. As these changes are heterogeneous, they also create the substrate for re-entrant arrhythmias.
- reduced Na^{+} channel density decreasing conduction velocity.
- increased expression of Na^{+}–Ca^{2+} exchanger protein, leading to intracellular Ca^{2+} overload and predisposition to delayed-after-depolarisation (DAD)-mediated arrhythmia.
- intercellular ion channels or connexins at gap junctions are decreased and redistributed from the intercalated disc to lateral cell borders, slowing conduction velocity and uncoupling myocytes.

Myocardial infarction scar produces:

- heterogeneous AP duration with zones of healing myocytes with shortened AP and surrounding hypertrophic myocytes with prolonged APs.
- potential anatomical circuits due to fibrous tissue separating myocyte bundles.

Arrhythmogenic mechanisms [4–6]

Many factors in isolation or combination give rise to the substrate of arrhythmogenesis (Fig. 31.3). Arrhythmia may arise from abnormalities of impulse generation or conduction. Table 31.2 demonstrates the relationship between the mechanism and type of arrhythmia and the desired antiarrhythmic effect.



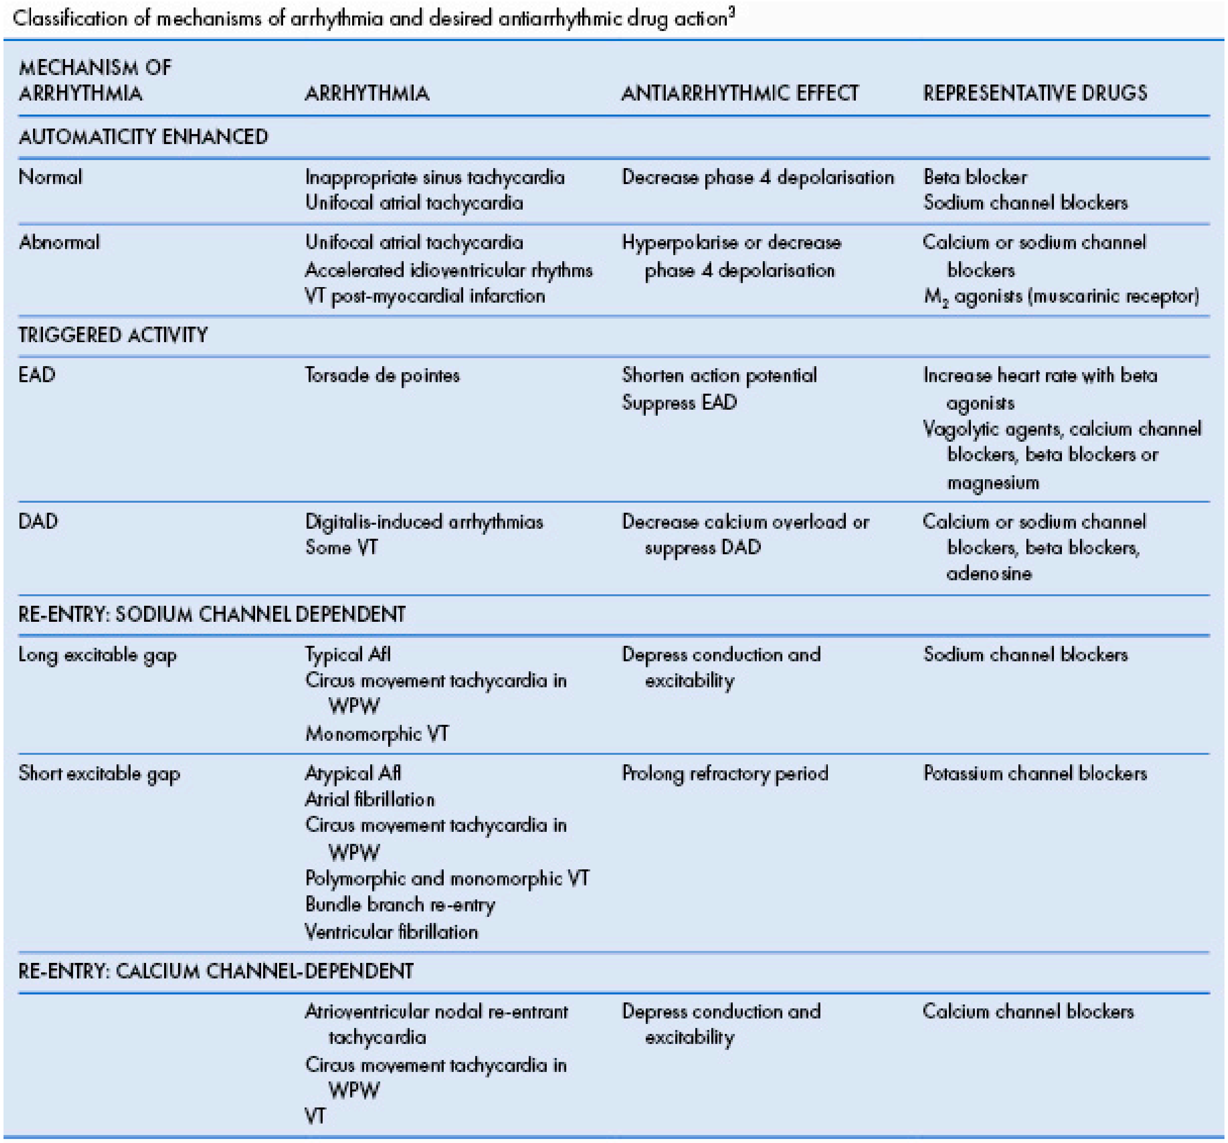
Structural influences
Transient influences
1 Myocardial infarction
• Acute
• Healed
• Aneurysm
2 Hypertrophy
3 Myopathic ventricle
• Dilation
• Fibrosis
Abnormal automacity
Slowed impulse conduction
Premature atrial and ventricular contractions
Arrhythmia
1 Transient ischaemia/ reperfusion
2 Systemic factors
• Hypoxia
• Acidosis
• Electrolyte abnormalities
3 Neurophysiological factors
• Autonomic tone
• Endogenous catecholamines
4 Toxicity
• Proarrhythmic drugs
• Exogenous catecholamines

The flowchart describes the causes of arrhythmia, divided into structural and transient influences. On the left side, under structural influences, there are three main categories. The first is myocardial infarction, which includes acute, healed, and aneurysmal types. The second is hypertrophy. The third is myopathic ventricle, which includes dilation and fibrosis. These lead to abnormal automaticity and slowed impulse conduction, which in turn causes premature atrial and ventricular contractions that result in arrhythmia. On the right side, transient influences are listed in four categories. The first is transient ischemia or reperfusion. The second is systemic factors, including hypoxia, acidosis, and electrolyte abnormalities. The third is neurophysiological factors, which include autonomic tone and endogenous catecholamines. The fourth is toxicity, which includes proarrhythmic drugs and exogenous catecholamines.

Both structural and transient influences converge to cause arrhythmia through similar mechanisms.

FIG. 31.3 Factors that combine to form the substrate of arrhythmogenesis.

Table 31.2



Classification of mechanisms of arrhythmia and desired antiarrhythmic drug action[3]

MECHANISM OF ARRHYTHMIA	ARRHYTHMIA	ANTIARRHYTHMIC EFFECT	REPRESENTATIVE DRUGS
AUTOMATICITY ENHANCED			
Normal	Inappropriate sinus tachycardia Unifocal atrial tachycardia	Decrease phase 4 depolarisation	Beta blocker Sodium channel blockers
Abnormal	Unifocal atrial tachycardia Accelerated idioventricular rhythms VT post-myocardial infarction	Hyperpolarise or decrease phase 4 depolarisation	Calcium or sodium channel blockers M_2 agonists (muscarinic receptor)
TRIGGERED ACTIVITY			
EAD	Torsade de pointes	Shorten action potential Suppress EAD	Increase heart rate with beta agonists Vagolytic agents, calcium channel blockers, beta blockers or magnesium
DAD	Digitalis-induced arrhythmias Some VT	Decrease calcium overload or suppress DAD	Calcium or sodium channel blockers, beta blockers, adenosine
RE-ENTRY: SODIUM CHANNEL DEPENDENT			
Long excitable gap	Typical AFl Circus movement tachycardia in WPW Monomorphic VT	Depress conduction and excitability	Sodium channel blockers
Short excitable gap	Atypical AFl Atrial fibrillation Circus movement tachycardia in WPW Polymorphic and monomorphic VT Bundle branch re-entry Ventricular fibrillation	Prolong refractory period	Potassium channel blockers
RE-ENTRY: CALCIUM CHANNEL-DEPENDENT			
	Atrioventricular nodal re-entrant tachycardia Circus movement tachycardia in WPW VT	Depress conduction and excitability	Calcium channel blockers

DAD , Delayed-after-depolarisation; *EAD* , early-AV blocking after-depolarisation; *VT* , ventricular tachycardia; *WPW* , Wolff–Parkinson–White syndrome.

Abnormal Impulse Generation (Table 31.3)

Enhanced Normal Automaticity

Automaticity is the property of spontaneous impulse generation by cardiac myocytes. This results from spontaneous depolarisation during phase 4. In the SA node and subsidiary pacemaker myocytes, phase 4 spontaneous depolarisation results from an inward current, predominantly Na^+ via the non-selective cation channel I_f. SA node discharge rate is influenced by changes to channel activity. Beta-adrenergic receptor stimulation increases both I_f and $I_{Ca\text{-}T}$ conductance and rate of phase 4 depolarisation by channel phosphorylation, whereas M_2 receptor increases I_k activity during phase 3 and early phase 4 to hyperpolarise myocytes, increasing time to reach depolarisation threshold.

Table 31.3

Causes of abnormal impulse generation

Enhanced normal automaticity	**Adrenergic stimulation**
Abnormal automaticity	Ischaemia
Early after-depolarisations	Hypoxia
	Hypercapnia
	Catecholamines
	Class IA antiarrhythmic drugs
	Class III antiarrhythmic drugs
	Other drugs that prolong repolarisation
Delayed after-depolarisations	Digoxin toxicity
	Increased intracellular Na^+
	Decreased extracellular K^+
	Increased intracellular Ca^{2+}
	Intracellular Ca^{2+} overload due to myocardial infarction or reperfusion after ischaemia

Enhanced normal automaticity of subsidiary atrial pacemakers, for example around pulmonary veins, is an increasingly recognised cause of atrial fibrillation (AF).

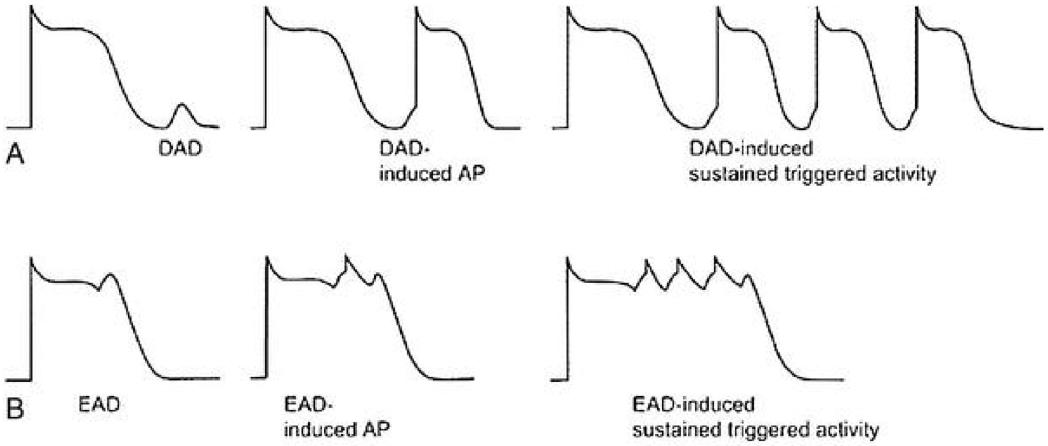
Abnormal Automaticity

Abnormal automaticity is the mechanism by which spontaneous impulses are generated in myocytes that are partially depolarised by a pathological process. The less negative RMP is associated with inactivation of the normal ionic currents of phase 4 depolarisation and the pacemaker current results from inward Na^+ and Ca^{2+} currents and is not readily susceptible to overdrive suppression from normal pacemaker activity. Due to this less negative membrane potential, these abnormal automatic myocytes inactivate the phase 0 fast inward Na^+ current, resulting in an impaired rate of impulse conduction (as well as contractility), which further contributes to arrhythmia. In this setting, Ca^{2+} carries the major inward current on depolarisation in these myocytes.

Triggered Activity

Abnormal impulse generation from triggered activity originates from oscillations in the membrane potential that are initiated or triggered by a preceding AP. There are two types of oscillations: EAD and DAD (Fig. 31.4). EAD occurs during phase 2 or 3 of the AP, whereas DAD occurs after the termination of depolarisation. The signal-averaged electrocardiograph (ECG) can detect after-depolarisations.

1. EADs appear as sub-threshold humps during the plateau or repolarisation phases. On reaching threshold, single or multiple APs can be induced. Plateau EADs are caused by an increased inward Ca^{2+} current (at this level of membrane potential, fast inward Na^+ channels are inactivated) and produce slow rising and propagating APs. Phase 3 EADs are caused by a reduction in outward K^+ currents and produce relatively rapidly rising and propagating APs. EAD amplitude and likelihood of triggered arrhythmia increase as driving rate decreases and AP is prolonged. Tachyarrhythmia induced by EAD is more likely to occur on the background of bradycardia.
2. DADs are produced by Na^+–Ca^{2+} exchanger current-induced oscillations in inward calcium current. These oscillations are caused by $[Ca^{2+}]_i$ overload saturating sarcoplasmic reticulum sequestration mechanisms, thereby leading to Ca^{2+}-induced Ca^{2+} release. Unlike EADs, DADs depend on previous rapid rhythm for their initiation.



The two sets of line graphs depict abnormal cardiac action potentials. Part A shows three graphs of delayed after depolarisation, progressing from a single event to induced and sustained triggered activity. Part B shows three graphs of early after depolarisation, also progressing from a single event to induced and sustained triggered activity. All graphs plot membrane potential over time.

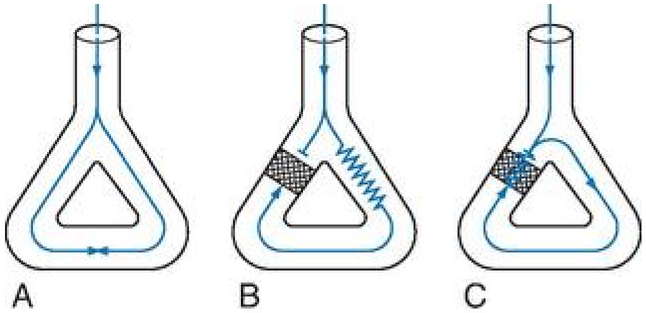
FIG. 31.4 Early- and delayed after-depolarisations. (A) DAD post repolarisation. (B) EAD delaying repolarisation (Reproduced from DeMazumder D, Tomaselli GF. Molecular and cellular mechanisms of cardiac arrhythmias. In: *Muscle* . Elsevier; 2012.)

Abnormal Impulse Conduction [7]

Normal cardiac rhythm is dependent on orderly homogeneous conduction throughout atrial and ventricular tissue. This orderly homogeneity of impulse conduction can be lost by abnormal physical barriers to conduction such as infarction scars or functional disturbances in AP leading to heterogeneity of impulse propagation. Magnitude and rate of depolarisation, presence of slow-response myocyte characteristics and rapidity of repolarisation influence speed of propagation. Functional disturbances in these properties are readily produced by channel receptor activation, ischaemia, hypertrophy and channel genetic mutation or expression.

Heterogeneity of impulse conduction may cause an arrhythmia by the phenomenon of re-entry. Re-entry describes the re-excitation of an area or entire heart by a circulating impulse. Although the classic ‘bifurcating Purkinje fibre’ model of Schmitt and Erlanger has given way to a much more complex picture, the essential electrophysiological requirements for re-entrant excitation remain. Requirements for re-entry are (Fig. 31.5):

- conduction block in one limb of the circuit
- slowed conduction in the other limb
- the impulse returns back along the limb initially blocked to re-enter and re-excite the pathway proximal to the block and complete the re-entry pathway.



The three triangular flasks labelled A, B, and C each demonstrate airflow using arrows. Flask A has an unobstructed triangular loop that allows smooth, continuous airflow. Flask B shows a mesh section on the side with a zigzag resistor symbol inside the loop. Flask C has a mesh at the same position, but the airflow is redirected through an alternative pathway, avoiding the triangular centre. All flasks have airflow that enters from the top and moves in distinct patterns within.

FIG. 31.5 Re-entrant excitation. (A) Normal cardiac impulse conduction results in the impulse being extinguished. (B) Conduction down one limb is blocked by segment of refractory tissue (excitable gap). (C) The impulse is conducted back up the limb and arrives at the excitable gap, which has recovered from refractoriness and retrograde conduction is complete. If geometry and electrical properties are favourable, the excitable gap circulates around the re-entry loop and arrhythmia is initiated.

When these properties are present, the chance of a circulating impulse producing re-entrant excitation depends on pathway geometry, the electrical properties and length of the depressed area and conduction velocity within each component. The segment of the re-entry pathway that is initially refractory and therefore blocks conduction down one limb and then recovers in time to conduct the return impulse is termed the ‘excitable gap.’ Therefore the generation and subsequent maintenance of a circuit depend on this excitable gap of non-refractory tissue circulating between the advancing depolarising wavefront and the repolarising tail. The resulting re-entrant impulse can be self-terminating; causing ectopic beats, or leads to atrial or ventricular tachyarrhythmia.

Risk of re-entry can be further modelled and quantified. Cardiac wavelength (λ) is the physical distance an electrical impulse travels in one refractory period; λ equals conduction velocity × refractory period (or AP duration). Re-entry is critically dependent on the λ being shorter than the potential re-entrant pathway. If λ exceeds the path length, then the advancing impulse encroaches on the refractory tail and re-entry is terminated. Reducing λ (decreasing conduction velocity or refractory period) promotes re-entry circuits.

Re-entry may be terminated by:

- *increasing conduction velocity:* the excitable gap is abolished by the wavefront arriving too early and meeting refractory tissue
- *increasing refractory period:* the excitable gap is lost
- *slowing conduction:* a unidirectional block can be converted into a complete block.

Ordered re-entry occurs along anatomical pathways which are ‘macroscopic’ loops (macro-re-entry), as in Wolff–Parkinson–White (WPW) syndrome. Functional circuits can be created following myocardial infarction, resulting in VT. ‘Microscopic’ loops (micro-re-entry) occur at the level of single fibres where antegrade and retrograde impulse propagation occurs in parallel fibres. Random re-entry refers to the generation of a circulating impulse, not from a fixed circuit but from constantly changing electrophysiologically distinct fibres or pathways created by the circulating impulse, resulting in AF or VF.

The cellular properties that lead to impaired conduction include:

- inactivation of the phase 0 fast Na^+ channels, which reduces both the magnitude and rate of propagation of any resultant AP
- intercellular uncoupling, which increases resistance to AP propagation and slows conduction. Intercellular coupling is reduced by ischaemia, $[Ca^{2+}]_i$ overload, acidosis and reduced

expression of intercellular ion channel connexin proteins in diseases such as chronic heart failure.

Ventricular Arrhythmia and the His–Purkinje System [8]

The Purkinje system is increasingly recognised as providing substrate for ventricular arrhythmia. Electrolyte imbalance, drugs and ischaemia during which Purkinje cells can survive in anaerobic conditions results in intracellular Ca^{++} overload, leading to enhanced automaticity and triggered arrhythmia. Triggered activity, EADs and DADs, originating in Purkinje cells during phases 2 and 3 initiate polymorphic VT and VF under these circumstances.

Recurrent ventricular arrhythmia, usually interspersed with periods of short-coupling ventricular ectopics (VEs) arising from Purkinje cells allows electrical mapping of triggered activity, usually along scar borders, enabling life-saving ablation in clinical situations such as ventricular arrhythmia following acute coronary syndromes or post-cardiac surgery.

The architecture of the Purkinje system in combination with areas of slowed conduction (drugs and ischaemia) can create re-entry pathways and substrate for monomorphic VT. The re-entry circuits can involve right and left bundle branches (bundle branch re-entry), single left fascicle (intrafascicle re-entry) or both left fascicles with intervening slower conducting myocardium (interfascicular re-entry). These discrete circuits can be localised by vulnerability to catheter touch and then induced or entrained by electrical pacing. The resulting VT can be terminated by programmed electrical stimulation and recurrence prevented by ablation.

Electrophysiological Effects of Ischaemia

Both hypoxia and acidosis are implicated in the production of a less negative RMP in ischaemia. A rise in extracellular K^+ results from impairment of the adenosine triphosphate (ATP)-dependent K^+ inward channels. As the K^+ concentration gradient ($[K^+]_o/[K^+]_i$) across the myocyte is the major determinant of the RMP, intracellular K^+ loss results in a less negative RMP.

The consequences of this are:

- abnormal automaticity
- inactivation of the fast inward Na^+ channels, which slows the conduction velocity.

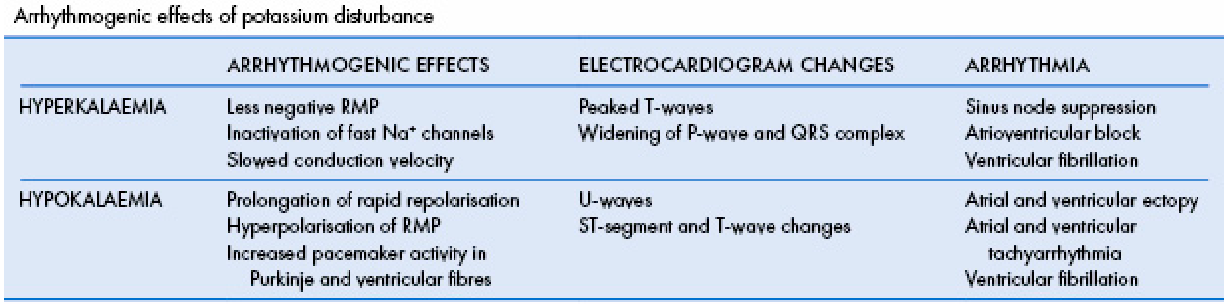
These arrhythmogenic effects of ischaemia are offset by activation of I_{KATP} K channels by ligand ADP binding, increasing phase 1 and 2 K repolarising current resulting in the antiarrhythmic action of shortening the AP.

Electrolyte Abnormalities and Arrhythmia [9]

Potassium

Hyper- and hypokalaemia both cause arrhythmia mediated by the resultant changes in RMP (Table 31.4). In ischaemia, hyperkalaemia at the local tissue level caused by a pathological extracellular shift of K^+ is the major factor contributing to ventricular arrhythmia in this setting. In hypokalaemia, the dispersion of pacemaker activity and the effect on repolarisation are similar to the electrophysiological effects of cardiac glycosides and beta-adrenergic agonists, and it is not surprising that a combination of these factors is associated with an increased incidence of arrhythmia. The increased risk of death in hypertensive patients treated with thiazide diuretics has been attributed to hypokalaemia (and possibly hypomagnesaemia)-induced arrhythmia (Multiple Risk Factor Intervention Trial). Thiazide-induced hypokalaemia ventricular ectopy is worsened by exercise. [10] Hypokalaemia is associated with VF and VT following acute myocardial infarction (AMI). The increased incidence of VF with a serum K^+ less than 3.5 mmol/L is clearly established and the probability of VT increases as the serum K^+ decreases. During AMI the incidence of VF/VT was 15% at 4.5 mmol/L, 38% at 3.5 mmol/L, 55% at 3.0 mmol/L and 67% at 2.5 mmol/L. [11]

Table 31.4



Arrhythmogenic effects of potassium disturbance

	ARRHYTHMOGENIC EFFECTS	ELECTROCARDIOGRAM CHANGES	ARRHYTHMIA
HYPERKALAEMIA	Less negative RMP Inactivation of fast Na^+ channels Slowed conduction velocity	Peaked T-waves Widening of P-wave and QRS complex	Sinus node suppression Atrioventricular block Ventricular fibrillation
HYPOKALAEMIA	Prolongation of rapid repolarisation Hyperpolarisation of RMP Increased pacemaker activity in Purkinje and ventricular fibres	U-waves ST-segment and T-wave changes	Atrial and ventricular ectopy Atrial and ventricular tachyarrhythmia Ventricular fibrillation

RMP, Resting membrane potential.

Magnesium

The antiarrhythmic properties of Mg^{2+} are clearly established, but a causal relationship between hypomagnesaemia and arrhythmia is largely circumstantial. Decreased extracellular Mg^{2+} by itself has little effect on the electrophysiological properties of myocytes or the ECG. Hypomagnesaemia has been implicated in the genesis of VT/VF in patients with hypertension and heart failure receiving thiazide or loop diuretics, acute alcohol intoxication or withdrawal and possibly with AMI. The product of K^+ and Mg^{2+} is the best predictor of arrhythmia in hypertensive patients taking thiazide diuretics.[12]

Autonomic Nervous System and Ventricular Arrhythmia [13]

The parasympathetic nervous system mediates vagal effect via I_{KACh}, muscarinic-gated K channels, which hyperpolarise cell membrane and decrease phase 4 depolarisation stabilising membrane potential decreasing rate and automaticity.

The autonomic nervous system, particularly vagal tone, also has a significant effect on the occurrence of post-myocardial infarction VF, as seen by the following:

- High vagal tone is associated with better outcomes and less susceptibility to exercise-induced VF with new ischaemia in animal models.
- Post-myocardial infarction exercise training results in an increased vagal tone, which inhibits inducible VF.
- Implantable electrical vagal stimulation and muscarinic agents, including edrophonium, are protective.
- The protection is not heart rate related, as the protection remains even when atrial pacing is used to maintain the heart rate.
- The administration of atropine increases the likelihood of developing VF.

Vagal tone can be measured by variability in the heart rate (RR interval) or blood pressure rise induced by the pressor agent phenylephrine. Heart rate variability is considered a measure of tonic vagal activity, whereas the phenylephrine method is considered a measure of magnitude of the vagal reflex in response to stimulus. A reduced vagal tone has been found post infarction in humans, which returns to normal over a 3–6-month period. There is no relationship between vagal tone and ejection fraction and the origin of reduced vagal tone post infarction appears to be due to afferent stimulation in response to necrotic tissue and impaired cardiac contractile geometry. This reduced vagal tone has also been shown to be predictive of mortality and inductility of arrhythmia in electrophysiological study (EPS).

Heterogeneity of Repolarisation: T-Wave Alternans [14]

Regional differences in repolarisation are associated with preconditions for conduction block, re-entry and life-threatening arrhythmias. This heterogeneity is seen in settings of impaired sarcoplasmic reticulum uptake of Ca^{2+} during ischaemia, drug proarrhythmia and congenital prolonged QT syndromes. In addition to prolonged QTc, ECG changes show variability of T-waves. This variability can manifest as visible T-wave alternans (TWA), defined as a beat-to-beat alternation in the morphology and amplitude of the ST segment or T-wave (Fig. 31.6).

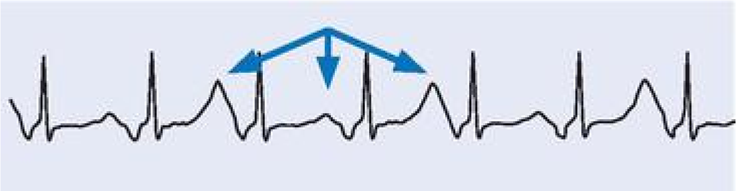


FIG. 31.6 Visible T-wave alternans and prolonged QT associated with heterogeneity of repolarisation.

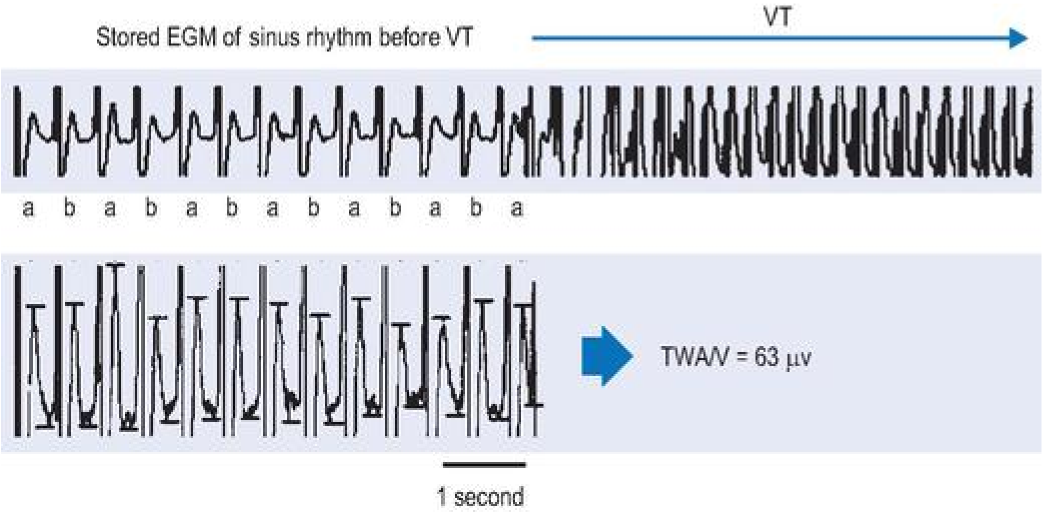
Computerised analytical methods for detecting non-visual TWA in the microvolt range have been developed for predicting the risk of ventricular tachyarrhythmia, sudden death and the need for implantable cardioverter defibrillators. TWA can be quantified as the moving average of beat-to-beat variation in T-wave amplitude (Fig. 31.7).



Stored EGM of sinus rhythm before VT
VT
a b a b a b a b a b a b a
TWA/V = 63 μv
1 second

The diagram contains two panels that show stored electrogram signals. The upper panel displays the progression from normal sinus rhythm to ventricular tachycardia as indicated by a long arrow labelled V T, which points rightward. The waveform segments are labelled with alternating a and b characters beneath each signal. The lower panel shows an enlarged view of the same waveform signals for clarity. A bold arrow on the right side points toward text reading T W A V equal to 63 microvolts, which represents T wave alternans. A horizontal scale at the bottom marks a time duration of one second.

FIG. 31.7 Example of heterogeneous repolarisation resulting in beat-to-beat microvolt fluctuation in T-wave amplitude measured by the Modified Moving Average method at 63 microvolts heralds the onset of ventricular tachycardia. *EGM* , Electrogram. (From American Heart Association, with permission.)

TWA may find a role in guiding drug therapy as a marker of antiarrhythmic effects and proarrhythmia. Despite significant promise, TWA has yet to find its way into routine practice.

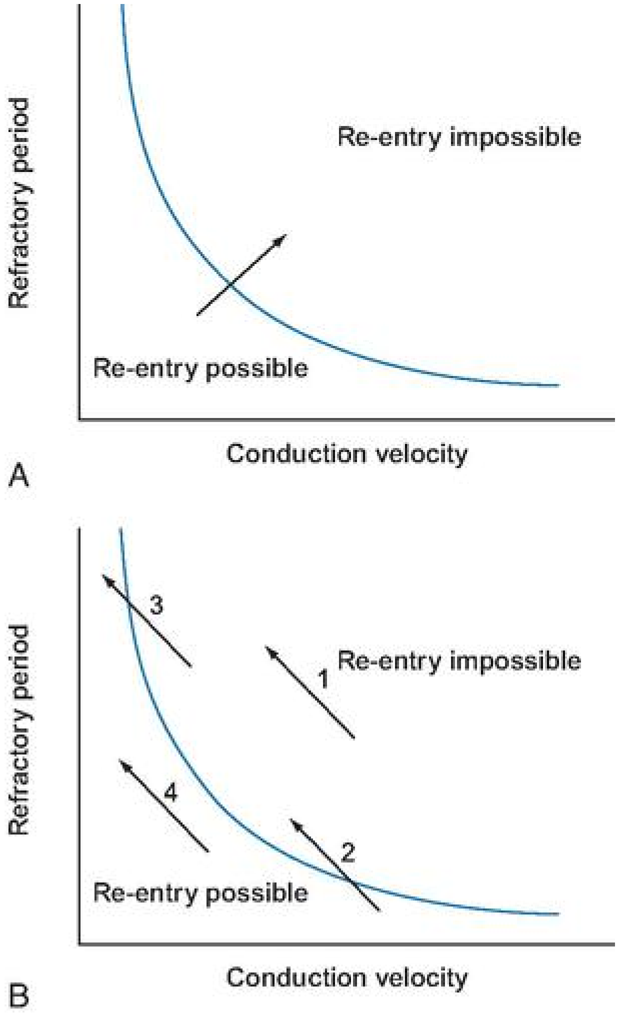
Proarrhythmic Effects of Antiarrhythmic Drugs [15, 16]

Proarrhythmia with the use of antiarrhythmic drugs is increasingly recognised. The ‘quinidine syncope’ due to VF and polymorphic VT at therapeutic concentrations was also seen with disopyramide. The Cardiac Arrhythmia Suppression Trial (CAST) clearly defined the magnitude of this deleterious side effect in drugs that were previously perceived to be of benefit. This study, which involved flecainide, encainide and moricizine (a class IA drug), was terminated early because of adverse outcomes in the flecainide and encainide groups (relative risk of arrhythmic death or non-fatal cardiac arrest of 3.6, 95% confidence interval [CI] 1.7–8.5). Proarrhythmia is reported between 5.9% and 15.8% depending on agent, clinical setting and definition of proarrhythmia, and now considered ubiquitous with all antiarrhythmic drugs.

Proarrhythmia has been defined as an increase in frequency of ventricular ectopic beat (VEB) or aggravation of the target arrhythmia on Holter monitor or exercise test. Manifestations of proarrhythmia not only include VEB, monomorphic and polymorphic VT and VF, but also bradyarrhythmias and atrial flutter (Afl) with 1:1 AV conduction. Most proarrhythmic events occur soon after starting the drug, but late arrhythmias are also a significant problem.

Proarrhythmia appears to be correlated with the degree of drug-induced QT prolongation, T-wave variability and characteristics of sodium channel blockade by the agent involved. Sodium channel-blocking agents with a long-time constant for recovery of the sodium channel blockade cause more pronounced blockade, even at slow heart rates, slow conduction to a greater extent and are associated with greater proarrhythmia. Agents with a short-time constant of sodium channel blockade, where sodium channel blockade is more pronounced at fast heart rates (e.g. class IB: lidocaine and mexiletine) are less proarrhythmic than drugs with long-time constants (e.g. class IC: flecainide and propafenone). Class III drugs and quinidine proarrhythmia correlate with the degree of QT prolongation.

The mechanism of drug proarrhythmia is probably via both slowing of conduction, triggered activity and abnormal automaticity. Paradoxically, slowing conduction, which may block a re-entry circuit, may also create the very substrate needed for re-entry, unidirectional block and an excitable gap. The existence of a re-entrant circuit requires the circulating wavefront of the impulse not to catch up with the refractory tissue behind the tail. Re-entry is more likely to occur with a shorter refractory period and reduced conduction velocity (Fig. 31.8).



The two graphs are labelled A and B. Both graphs have the refractory period on the vertical axis and conduction velocity on the horizontal axis. Each graph shows a curved line sloping downward from left to right, dividing two regions. The upper region is labelled re-entry impossible, and the lower region is labelled re-entry possible. In graph A, an arrow points from the re-entry impossible region to the re-entry possible region. In graph B, four arrows are labelled 1 to 4 and show movement between the regions from right to left across the refractory period.

FIG. 31.8 (A) Graph of refractory period of an excitable gap versus its conduction velocity around a theoretical re-entrant circuit. When conduction velocity is high enough so that refractory period of excitable gap exceeds circuit time, re-entry is impossible. *Arrow* demonstrates the action of an 'ideal' antiarrhythmic drug, which prolongs the refractory period and increases conduction velocity. (B) With antiarrhythmic drugs that increase the refractory period and slow conduction, the net effect of an antiarrhythmic drug may have no effect on proarrhythmia *(arrows 1 and 4)* , decrease proarrhythmia *(arrow 2)* or increase proarrhythmia *(arrow 3)* depending on properties of a potential re-entrant circuit. (Adapted from Schwartz PJ, La Rovere MT, Vanoli E. Autonomic nervous system and sudden cardiac death. *Circulation* . 1992;85(suppl 1):77–91, with permission.)

Increasing conduction velocity is an ideal antiarrhythmic property but there are no antiarrhythmic drugs that accelerate conduction. However, antiarrhythmic drugs readily slow conduction and the degree of conduction slowing and therefore proarrhythmia tendency correlates with the potency of antiarrhythmic properties.

Prolonging the refractory period is also an ideal antiarrhythmic property, which increases the likelihood of abolishing any excitable gap by ensuring the wavefront of a re-entrant circuit meets refractory tissue. The potency of class IA and III antiarrhythmic agents is dependent on the prolongation of the refractory period. This property is also protective against proarrhythmia due to re-entry mechanism. The effect of class IB agents on shortening the refractory period will contribute to proarrhythmia by this mechanism in this class.

Surface mapping of the heart has been used to quantify proarrhythmic effects. The scale of potency of proarrhythmia has been found to be:

flecainide > propafenone > quinidine > disopyramide
> procainamide > mexiletine > lidocaine > sotalol

Amiodarone was not included in this study but presumably, its proarrhythmic potential is similar to other class III agents and less than the class I agents.

Antiarrhythmic drugs are effective at suppressing abnormal automaticity, with the exception of triggered automaticity due to EAD. Class IA, class III and many non-antiarrhythmic drugs can produce proarrhythmia via EAD. These drugs increase not only the frequency of EAD but also the likelihood of them leading to triggered tachyarrhythmia. Slowing repolarisation, which leads to QT prolongation and slower heart rate, is central to this increased frequency and sensitivity to EAD. EAD manifests as prominent and bizarre T-U waves on the ECG and, if triggered activity results, VEB and ventricular tachyarrhythmia may occur. Torsade de pointes is the classical resulting arrhythmia, although less classical polymorphic VT and VF can result. Risk of proarrhythmia via this mechanism correlates with the degree of QT prolongation.

All antiarrhythmic drugs are capable of producing bradyarrhythmia via decreasing normal automaticity and slowing conduction. Digoxin can be proarrhythmic via the production of triggered activity due to DAD.

Antiarrhythmic drug proarrhythmia is facilitated by several factors which are frequently found in patients on antiarrhythmic drugs or with heart disease (Box 31.1).

Box 31.1

Factors facilitating antiarrhythmic drug proarrhythmia [13]

Toxic blood levels due to excessive dose or reduced clearance from old age, heart failure, renal disease or hepatic disease

Severe left ventricular dysfunction; ejection fraction less than 35%
Pre-existing arrhythmia or arrhythmia substrate
Digoxin therapy
Hypokalaemia or hypomagnesaemia
Bradycardia

Combinations of antiarrhythmic drugs and concomitant drugs with similar toxicity

Management of the Patient With a Cardiac Arrhythmia

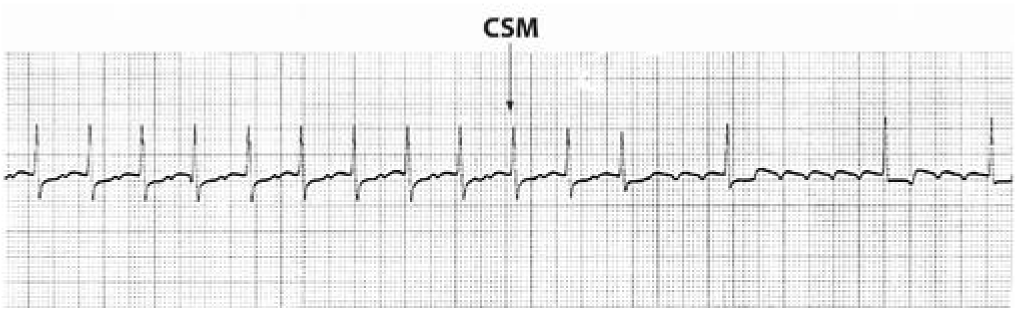
History and Physical Examination

A careful history is important. Specific questions should confirm or exclude palpitations, syncope, chest pain, shortness of breath, ischaemic heart disease (especially previous myocardial infarction), congestive cardiac failure, valvular heart disease, thyrotoxicosis and diuretic therapy without adequate potassium supplements. A family history is helpful for arrhythmias associated with inherited disorders (e.g. LQTS and hypertrophic obstructive cardiomyopathy). The physical examination looks for underlying structural heart disease and signs to assist diagnosis and assesses haemodynamic consequences of the arrhythmia.

Vagal Manoeuvres

Vagal manoeuvres may be undertaken during the examination. These reflexly increase vagal tone, thereby prolonging AV node conduction and refractoriness. The effect may be:

- transient slowing of sinus tachycardia as SA nodal discharge rate is slowed
- termination of AV nodal re-entry tachycardia (AVNRT) and AV re-entry tachycardia (AVRT)
- unmasking (but not reversion) of atrial tachycardia, flutter (Fig. 31.9) and fibrillation.



The E C G strip on grid paper shows a continuous, evenly spaced waveform pattern. The waveforms initially show a regular and rapid rhythm. At the centre top of the strip, there is a bold label that reads C S M, with a downward-pointing arrow at the waveform. Immediately following this point, the waveform rhythm slows noticeably. The waveforms after the C S M point become wider spaced and less frequent. The entire strip is aligned horizontally on E C G graph paper, which shows the transition in heart rate across the time interval.

FIG. 31.9 Atrial flutter with 2:1 atrioventricular (AV) block. Carotid sinus massage *(CSM)* increases AV block to 4:1, then 6:1.

VT is not affected. Carotid sinus massage has been commonly used in the past. Valsalva manoeuvre or iced water to the face may be useful. Eyeball pressure should be avoided as eye damage may result.

Increasingly, the Valsalva manoeuvre is recommended. Maximum vagal effect is achieved with supine positioning and a Valsalva manoeuvre of 15 seconds duration and a pressure of 40 mm Hg (5.32 kPa) with an open glottis. An adequate Valsalva manoeuvre method can be achieved by getting the patient to blow into a 10 mL syringe in an attempt to move the plunger.

Investigations

A 12-lead ECG should be recorded with a longer rhythm strip (usually lead II or V_1). If P-waves are not visible, atrial activity may be recorded using an oesophageal electrode or pacing lead, or via a central venous catheter or the right atrial injectate port of a pulmonary artery catheter, using 20% saline and a bedside monitor.[17]

Holter monitoring requires prolonged (usually 24–72 hours), non-invasive, ambulatory ECG monitoring, sometimes combined with exercise testing. For infrequent symptoms suggestive of arrhythmia, implantable loop recorder can be inserted and interrogated. EPS, which involves invasive electrophysiological testing with programmed electrical stimulation, attempts to reproduce the spontaneously occurring arrhythmia.[18, 19] EPS is not clearly superior to Holter monitoring in evaluating drug treatment for ventricular arrhythmias. Other investigative techniques being studied include signal-averaged ECG, heart rate variability and electrical alternans measurement.[13, 20]

Management of specific arrhythmias

Treatment has two aspects: acute termination of the arrhythmia and long-term prevention. The decision on whether to treat depends on the rhythm diagnosis, haemodynamic consequences, aetiology of the arrhythmia and the prognosis (e.g. risks of sudden death or long-term complications).

Ectopic Beats

These are premature impulses originating from the atria, AV junction, Purkinje system or ventricles. The coupling interval (time between the ectopic and the preceding beat) is shorter than the cycle duration of the dominant rhythm.

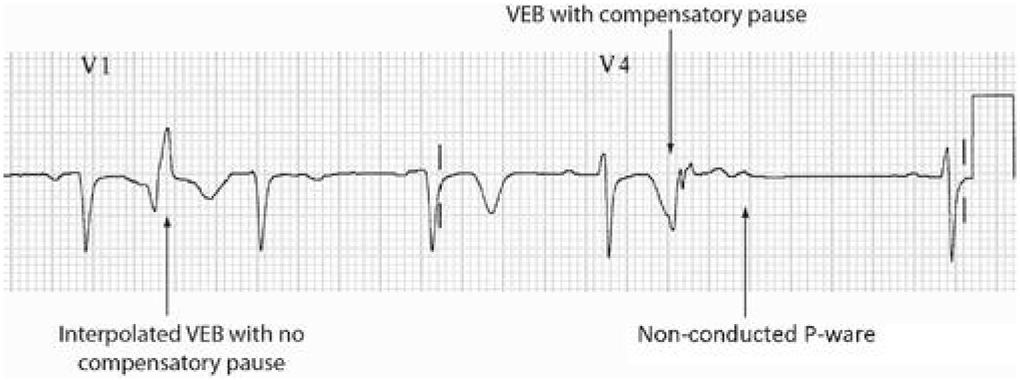
Premature Ventricular Ectopic Beats

These are also known as ventricular premature beats and ventricular premature complexes. The ventricle is not activated by the normal rapidly conducting bundle branches and a wide QRS complex results from slow ventricular conduction.

ECG

There is no preceding P-wave.

- Premature complexes occur before the next expected QRS.
- QRS is wide (>120 ms).
- T-wave of opposite polarity to the QRS (Fig. 31.10).
- VEB is not conducted retrogradely to the SA node.
- SA node is therefore not reset, and there is temporary AV dissociation with a full compensatory pause; the interval between the normal QRS complexes on either side of the VEB will usually be twice that of the dominant sinus rhythm.



VEB with compensatory pause
V1
V4
Interpolated VEB with no compensatory pause
Non-conducted P-ware

The E C G strip displays three notable findings: on the left, an interpolated ventricular ectopic beat with no compensatory pause, in the centre, a V E B with a compensatory pause, and on the right, a non-conducted P wave. The leads V 1 and V 4 are labelled, and the events are annotated with arrows and descriptions. The tracing highlights different arrhythmic behaviours and conduction abnormalities in a continuous E C G rhythm strip.

FIG. 31.10 Sinus rhythm with an interpolated ventricular ectopic beat *(VEB)* without a compensatory pause and a VEB with a following non-conducted P-wave, resulting in a compensatory pause.

Occasionally VEBs may not produce any pause and are said to be interpolated (see Fig. 31.10). Interpolated VEBs occur when the background sinus rhythm is slow. The retrograde conduction into the AV node renders it partially refractory to the next impulse and its conduction through the AV node is slowed and the PR interval is prolonged. A VEB following each sinus beat is ventricular bigeminy. Ventricular trigeminy refers to recurring sequences of a VEB followed by two sinus beats. Two VEBs in succession are a couplet, and three, a triplet.

Clinical

Even when frequent, complex, or in short runs of non-sustained VT, VEBs are not associated with risk of sudden death in asymptomatic healthy adults.[21] However, there is an increased risk of cardiovascular death with:

- *exercise-induced VEB:* risk of death 2.53 (95% CI 1.65–3.88)[22]
- *AMI and VEB:* frequent and complex VEBs often precede VF or sustained VT and are a marker of risk of subsequent SCD.

Apart from ischaemic heart disease, VEB may be associated with cardiomyopathy, valvular disease, myocarditis and non-cardiac precipitating factors (e.g. electrolyte and acid-base disturbances, hypoxia and drugs such as digoxin).

Treatment

Drug treatment of VEB is rarely indicated and may be dangerous.

- Correct potassium and magnesium.
- Severely symptomatic patients with frequent complex VEB may benefit from judicious beta blockade.
- The underlying cause of VEB is often more clinically relevant than the arrhythmia. Following myocardial infarction, beta-adrenergic blockers, which are indicated for long-term benefit, will also likely suppress VEB.
- Prophylactic lidocaine following AMI will increase total mortality and has been abandoned.[23], [24]
- Attempts at long-term VEB suppression with class IC agents (flecainide and encainide), even if successful, increase mortality.[15]

Supraventricular Tachycardias (Box 31.2)[25]

Supraventricular tachycardia (SVT) is any tachycardia that requires atrial or AV nodal tissue for initiation and maintenance.

- SVTs are usually conducted rapidly through the bundle branches so that QRS complexes are narrow.

- All narrow-complex tachycardias are SVT and wide-complex tachycardias are usually ventricular.
- However, SVT may be widely complex in the setting of bundle branch block (BBB) and pre-excitation.

Box 31.2

Classification of supraventricular tachycardia

Atrioventricular (AV) node dependent

AV nodal re-entry tachycardia : re-entry within the AV node
AV re-entry tachycardia : re-entry includes accessory pathway between atria and ventricles
Accelerated idionodal rhythm : increased automaticity of AV node

AV node independent

Afl: re-entry confined to atria
Atrial fibrillation: multiple re-entry circuits confined to atria
Unifocal atrial tachycardia: usually due to increased automaticity
Multifocal atrial tachycardia: increased automaticity or triggered activity
Others: sinus node re-entry tachycardia
Afl , Atrial flutter

A clinically useful classification divides SVTs into AV node-dependent and AV node-independent. Distinguishing between AV node-dependent and independent SVTs can be difficult. Vagal manoeuvres or drugs that prolong AV nodal refractoriness (e.g. adenosine) may assist in diagnosis [26] :

- Temporary AV block with unchanged atrial rate indicates AV node independence.
- Slowing or reversion of the tachycardia diagnoses AV dependence.

AV Node-Dependent SVT

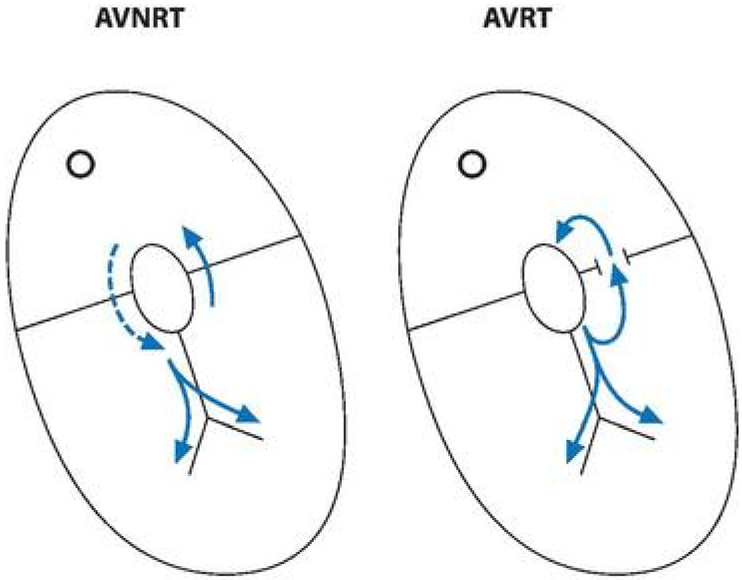
In these SVTs, sometimes referred to as junctional tachycardia, the re-entry circuit or ectopic focus involves the AV node or junction. Blocking the AV node with drugs such as adenosine or vagal manoeuvres will terminate these SVTs.

AV Node-Independent SVT

Also referred to as atrial tachycardia, the atrial tissue only is required for the initiation and maintenance of the tachycardia. Blocking the AV node will not terminate these SVTs; it will merely slow the ventricular rate.

AV Nodal Re-Entry Tachycardia (Fig. 31.11)

Re-entry tachycardia is confined to the AV node. Antegrade conduction to the ventricles usually occurs over the slow pathway and retrograde conduction over the fast pathway.



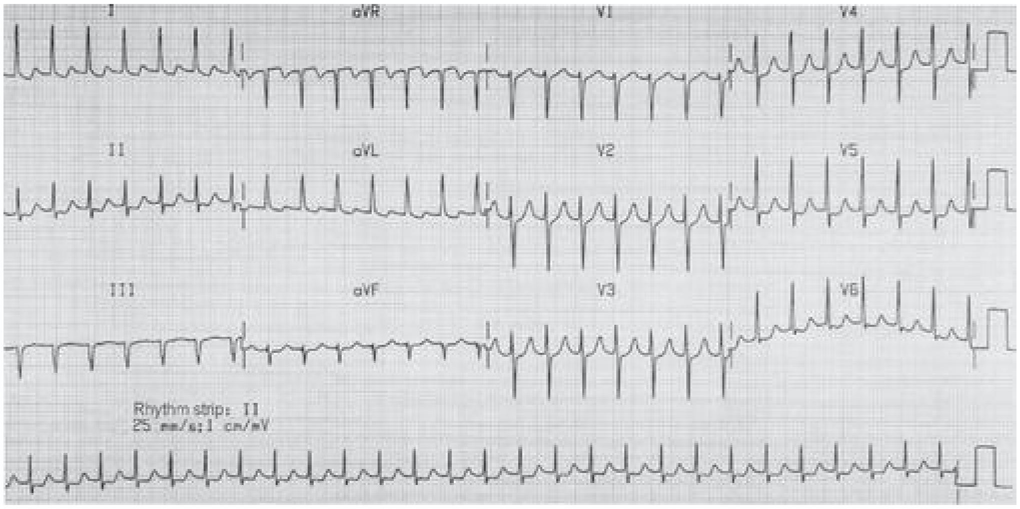
Acute therapy	• Vagal manoeuvre • Adenosine
Chronic therapy	• Catheter ablation • β blockers • Class Ic • Class III

The two diagrams, labelled A V N R T and A V R T, illustrate the pathways of atrioventricular nodal reentrant tachycardia and atrioventricular reentrant tachycardia. Each diagram shows circular reentrant circuits with arrows marking the direction of electrical conduction. A V N R T involves a reentrant loop within or near the A V node, while A V R T involves a reentrant loop using an accessory pathway. Below the diagrams, therapies are listed, such as Acute therapy includes vagal manoeuvre and adenosine, Chronic therapy includes catheter ablation, beta blockers, Class one c, and Class three antiarrhythmic drugs.

FIG. 31.11 Atrioventricular nodal re-entry tachycardia (AVNRT) has both pathways in the AV node. The conduction occurs over the slow pathway and retrogradely over the fast pathway. AV re-entry tachycardia (AVRT) involves antegrade conduction through the AV node and retrograde conduction through an accessory pathway.

ECG

There is regular narrow-complex tachycardia (140–220 beats/min) with abrupt onset and termination. P-waves are not usually observed as they are buried in the QRS complexes (Fig. 31.12).



The electrocardiogram shows a standard twelve-lead format with limb leads one, two, three, a V R, a V L, a V F, and precordial leads V1, V2, V3, V4, V5, V6. There is a rapid, regular rhythm with narrow Q R S complexes visible in all leads. P waves are not clearly discernible. The tracing includes a rhythm strip in lead two at the bottom, showing consistent narrow Q R S complexes with a rate above one hundred fifty beats per minute.

FIG. 31.12 Atrioventricular nodal re-entry tachycardia. Narrow QRS tachycardia at 160 beats/min. P-waves are not apparent and are buried in the QRS complex.

Clinical

AVNRT is a common arrhythmia that is not usually associated with structural heart disease. The major symptom is palpitations.

Treatment

Vagal manoeuvres slow conduction through the AV node and may ‘break’ the tachycardia. If vagal manoeuvres fail, adenosine is the drug of choice and nearly all AVNRT will revert with adenosine. [24, 26] Verapamil has been used in the past but causes hypotension, which may be prolonged if cardiac function is depressed or patients are receiving beta-adrenergic blockers. Sotalol, amiodarone and flecainide may also be effective but are rarely used. Rapid atrial pacing will usually terminate AVNRT but is rarely needed.

Cardioversion is occasionally necessary when drugs are ineffective or when severe haemodynamic instability is present.

Prevention

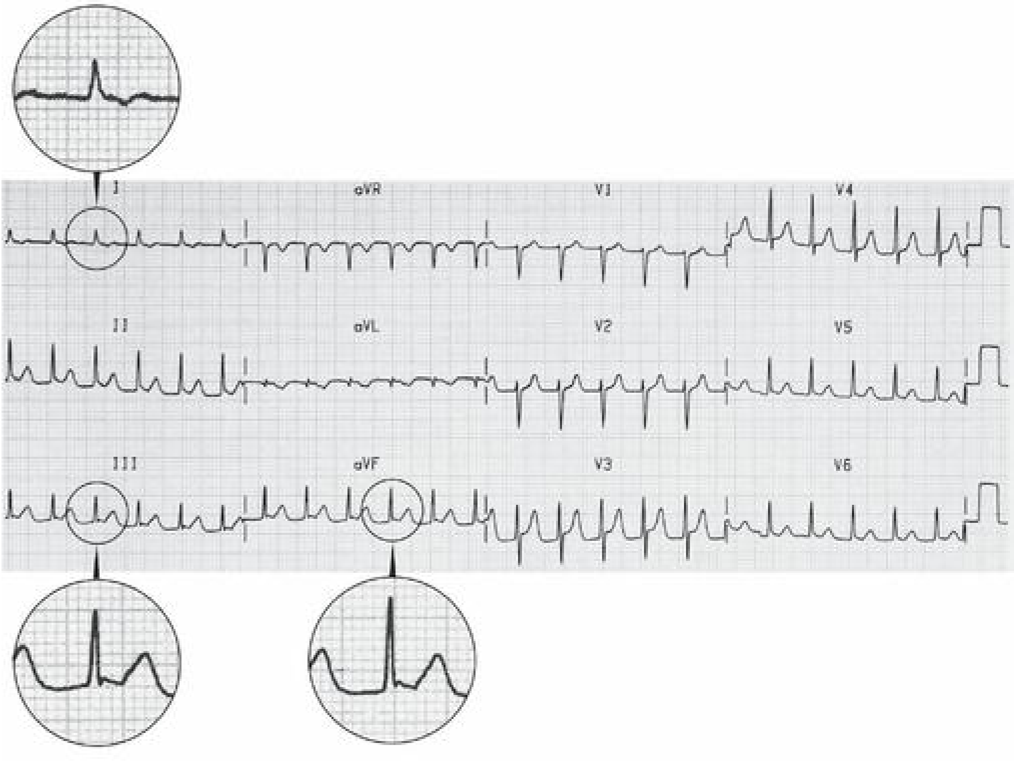
Troublesome recurring episodes of AVNRT can be cured by radiofrequency ablation, using a transvenous catheter to interrupt the re-entrant circuit permanently.

AV Re-Entry Tachycardia (See Fig. 31.11)

The re-entry pathway consists of the AV node and an accessory pathway, which bypasses the AV node. The accessory pathway may be evident during sinus rhythm, with the ECG showing pre-excitation: short PR interval, delta wave and widening of the QRS (see WPW, below, under Pre-excitation syndrome). However, in 25% of cases, the accessory pathway conducts only retrogradely from ventricle to atria and the ECG pre-excitation will be concealed in sinus rhythm. Orthodromic AVRT, with antegrade nodal and retrograde accessory pathway circuits, is the most common regular SVT in patients with accessory pathways.

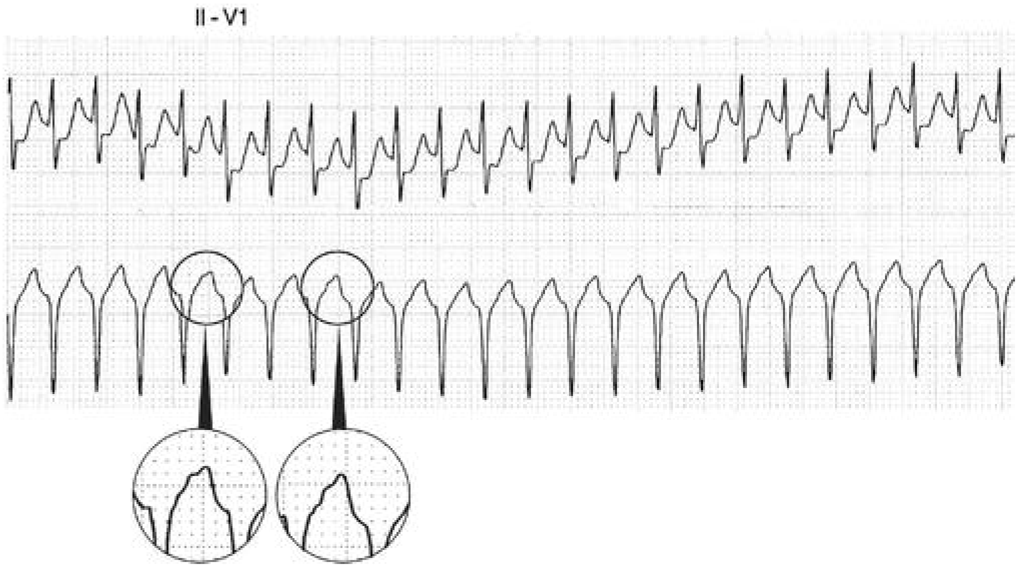
ECG

The ECG is similar to AVNRT. The length of the re-entry circuit is, however, greater and the accessory AV pathway is some distance from the AV node. It therefore takes longer for the impulse to be conducted backwards to the atria, and so the retrograde P-wave usually occurs after the QRS, sometimes at some distance, and is inverted in leads II, III and aVF (Figs. 31.13 and 31.14).



The electrocardiogram includes twelve standard leads one, two, three, a V R, a V L, a V F, and V1 through V6. Atrial activity is emphasised using circular magnified insets, highlighting the P wave abnormalities in multiple leads, including lead two, lead V1, and lead V3. The insets show enlarged and bifid or notched P waves, consistent with left atrial enlargement or atrial conduction delay. The rhythm appears regular, with normal narrow Q R S complexes and upright T waves in most leads.

FIG. 31.13 Atrioventricular re-entry tachycardia. Narrow QRS tachycardia at 135 beats/min. Inverted P-wave in leads I, II, III and aVF just following the QRS complex.



The E C G rhythm strip shows continuous leads two and V 1 with a regular, fast rhythm. Narrow Q R S complexes exceed one hundred fifty beats per minute. P waves are not visible before the Q R S but appear retrogradely after the Q R S complexes, as shown in magnified insets.

FIG. 31.14 Atrioventricular re-entry tachycardia. Rate is 214 beats/min. P-wave deflection is just seen on the upslope of the T-wave in lead V_1.

Clinical

AVRT is similar to AVNRT, although antegrade conduction over the accessory pathway may be very rapid with WPW if AF occurs.

Treatment [23, 26]

Acute treatment is identical to AVNRT, but verapamil should be avoided in WPW syndrome, as it may block the AV node, facilitating very rapid conduction to the ventricles via the accessory pathway. [27]

Prevention

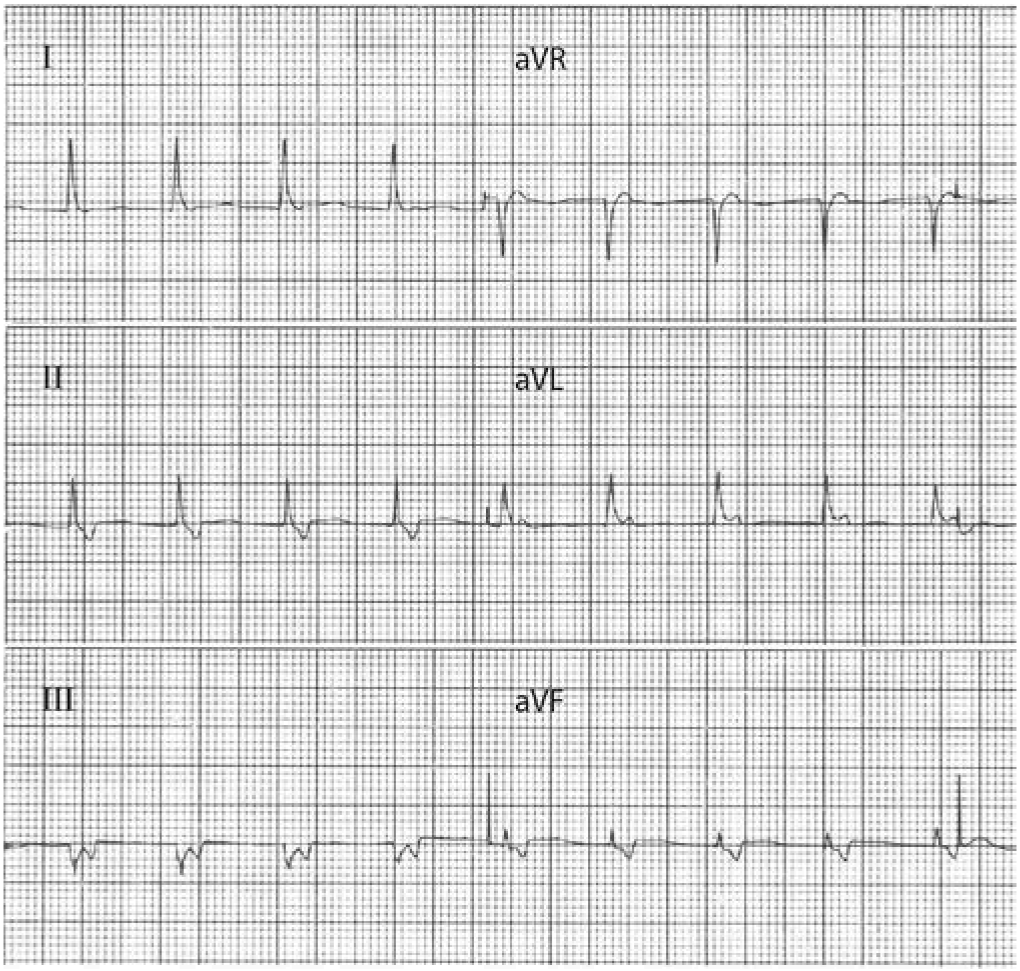
Drugs such as sotalol and flecainide may prevent recurrence of the tachycardia. Radiofrequency ablation of the accessory pathway is usually curative.

Accelerated Idionodal Rhythm

Increased automaticity of the AV junction (above the inherent discharge rate of 40–60 beats/min) is the usual cause of this arrhythmia. The often-used term ‘non-paroxysmal AV junctional tachycardia’ is cumbersome and misleading: junctional rate is commonly 60–100 beats/min, not strictly a tachycardia. AV dissociation is often present, but there may be synchronisation of the two pacemakers – so-called isorhythmic dissociation.

ECG

There are narrow complexes on the ECG at a regular rate (60–130 beats/min) (Fig. 31.15), often with independent atrial activity. With isorhythmic dissociation, the P-wave is either fixed relative to the QRS complex (usually just after) or oscillates to and fro across the QRS in a rhythmical manner.



The E C G displays limb leads one, two, three, a V R, a V L, a V F. The rhythm is regular with upright P waves preceding each narrow Q R S complex. No S T segment elevation or depression is noted. T waves appear normal in morphology and axis across all six leads. The tracing is printed on standard electrocardiogram grid paper.

FIG. 31.15 Accelerated idionodal rhythm: 105 beats/min. Inverted P-wave is immediately following the QRS complex in leads II, III and aVF.

Clinical

It may be observed in normal persons but is often associated with structural heart disease, especially following inferior myocardial infarction. Digoxin intoxication is another important cause.

Treatment

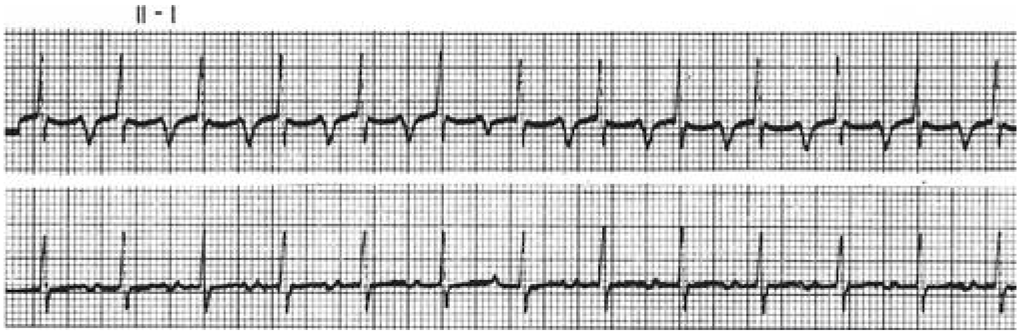
In most cases, the rhythm is transient and well tolerated, and no treatment is required. Treatment is otherwise directed towards the underlying cause.

Unifocal Atrial Tachycardia

This is sometimes called ectopic atrial tachycardia to distinguish it from atrial tachycardia (referring collectively to unifocal atrial tachycardia, Afl and AF). However, it is inappropriate to call atrial tachycardia paroxysmal atrial tachycardia. Paroxysmal, by definition, indicates an abrupt onset and termination, which applies less commonly to unifocal atrial tachycardia. Vagal manoeuvres will not terminate this arrhythmia, but AV block may be induced, or increased if already present.

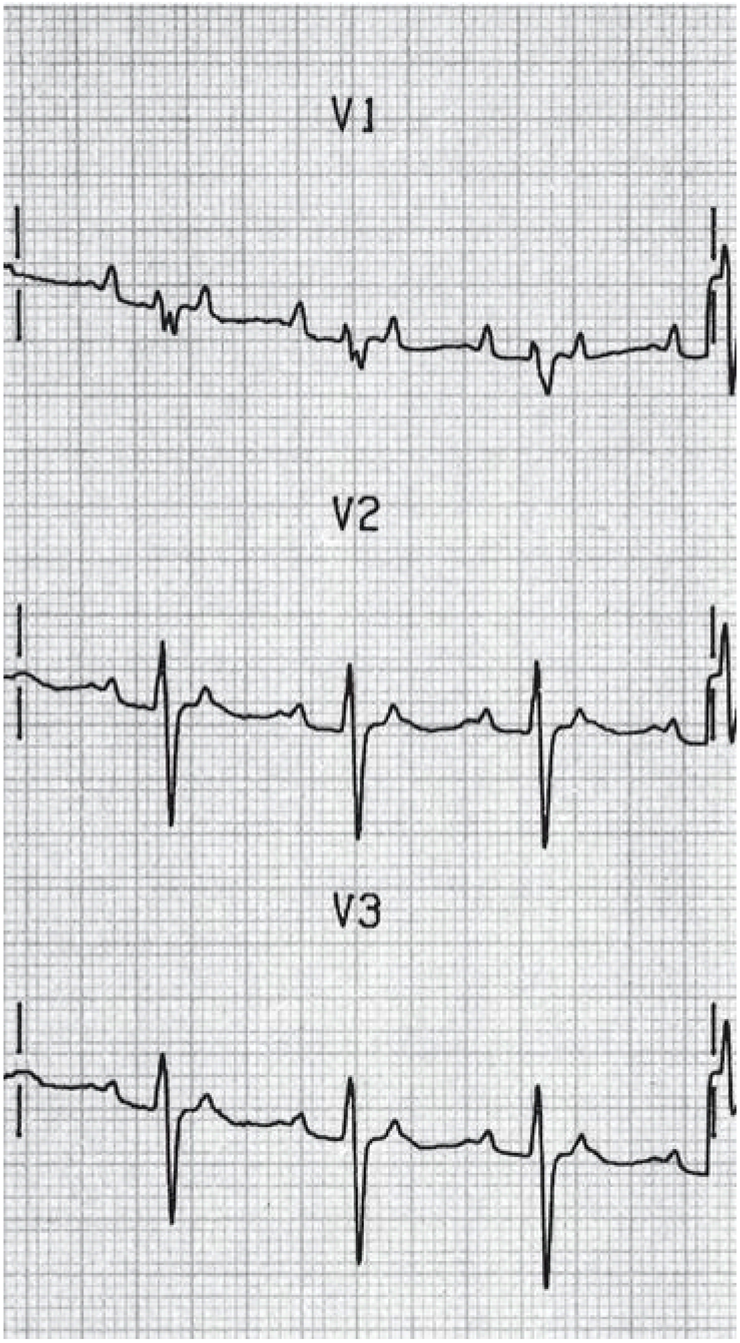
ECG

P-wave morphology is abnormal but monomorphic. Atrial rate is often 130–160 beats/min, and may occasionally exceed 200 beats/min. Atrial rate distinguishes unifocal atrial tachycardia from Afl, with Afl greater than 250 beats/min. The QRS complexes will usually be narrow (Fig. 31.16). AV block is common (Fig. 31.17).



The E C G rhythm strip displays leads two and one in two continuous rows. The tracing shows a regular rhythm with narrow Q R S complexes and upright P waves consistently preceding each complex. T waves are upright and symmetric. No S T segment depression or elevation is visible. The waveform amplitude and intervals appear within normal limits.

FIG. 31.16 Unifocal atrial tachycardia with 1:1 atrioventricular conduction; rate is 140 beats/min. Large, inverted P-waves are seen in lead II.



The E C G displays precordial leads V 1, V 2 and V 3. S T segment elevation is noted in leads V 1 and V 2 with upright T waves. Q R S complexes are narrow and preceded by clear P waves. No pathologic Q waves are present.

FIG. 31.17 Unifocal atrial tachycardia with 2:1 atrioventricular conduction. Atrial rate is 170 beats/min.

Clinical

Digitalis intoxication is the most common cause, especially when AV block is present. Other causes include myocardial infarction, chronic lung disease and metabolic disturbances.

Treatment [23]

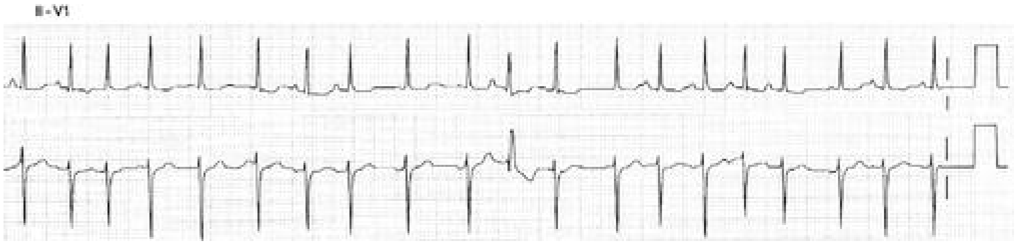
If applicable, digitalis is stopped and the toxicity treated. Otherwise, digoxin may be used to control the ventricular rate. Beta-adrenergic blockers or amiodarone are alternatives. Rapid atrial pacing may be ineffective if the arrhythmia is due to increased automaticity, although it may increase AV block, thereby slowing ventricular rate. Synchronised DC shock may be necessary, but is avoided if digitalis intoxication is suspected.

Multifocal Atrial Tachycardia [28]

Multifocal atrial tachycardia (MAT) is defined as an atrial rhythm with a rate greater than 100 beats/min, with organised, discrete non-sinus P-waves having at least three different forms in the same ECG trace. The baseline between P-waves is isoelectric, and the PP, PR and RR intervals are irregular. This is an uncommon arrhythmia, also known as chaotic or mixed atrial tachycardia.

ECG

There are irregular atrial rates, usually 100–130 beats/min, with varying P-wave morphology (at least three different P-wave morphologies and varying PR interval) and some degree of AV block (Fig. 31.18). Most P-waves are conducted to the ventricles, usually with narrow QRS complexes.



The E C G rhythm strip includes leads two and V 1. The first row shows regular narrow Q R S complexes with upright P waves indicating normal sinus rhythm. In the second row, there is a sudden transition to wide complex tachycardia with broad Q R S complexes. No visible P waves are seen preceding these wide complexes. The Q R S morphology differs from the initial rhythm.

FIG. 31.18 Multifocal atrial tachycardia with the rate of about 130 beats/min. There are varying P-wave morphology and PR intervals. Note the wide complex preceded by a P-wave. The aberrant intraventricular conduction is related to the long-short cycle length sequence.

Clinical

MAT is often misdiagnosed and inappropriately treated as AF. This rhythm occurs most commonly in critically ill elderly patients with chronic lung disease and cor pulmonale and is associated with a very high mortality from underlying disease. Theophylline has been implicated as a precipitating cause, and rarely, digoxin.

Treatment

Treatment should correct the underlying cause (e.g. treatment of cardiorespiratory failure, electrolyte and acid-base abnormalities and theophylline toxicity). Spontaneous reversion is common, and few patients require antiarrhythmic therapy. Magnesium is the drug of choice for acute control. [29] Beta blockers are probably more effective than diltiazem, but because of the common association of MAT with obstructive lung disease have limited utility. Digoxin and cardioversion are ineffective, which highlights the need to differentiate MAT from AF. Longer-term control is best achieved with diltiazem in patients with good left ventricular (LV) function and amiodarone in those without.

Atrial Flutter [30]

Afl is an intra-atrial macro-re-entrant arrhythmia with an impulse and contraction wave circulating the atrium at rates of 250–350 beats/min, and in most cases, close to 300 beats/min. Afl occurs at about one-tenth the frequency of AF, often coexisting with AF, with 56% eventually developing AF. Afl is more common in males and incidence increases with age. Conditions associated with Afl are shown in Box 31.3 .

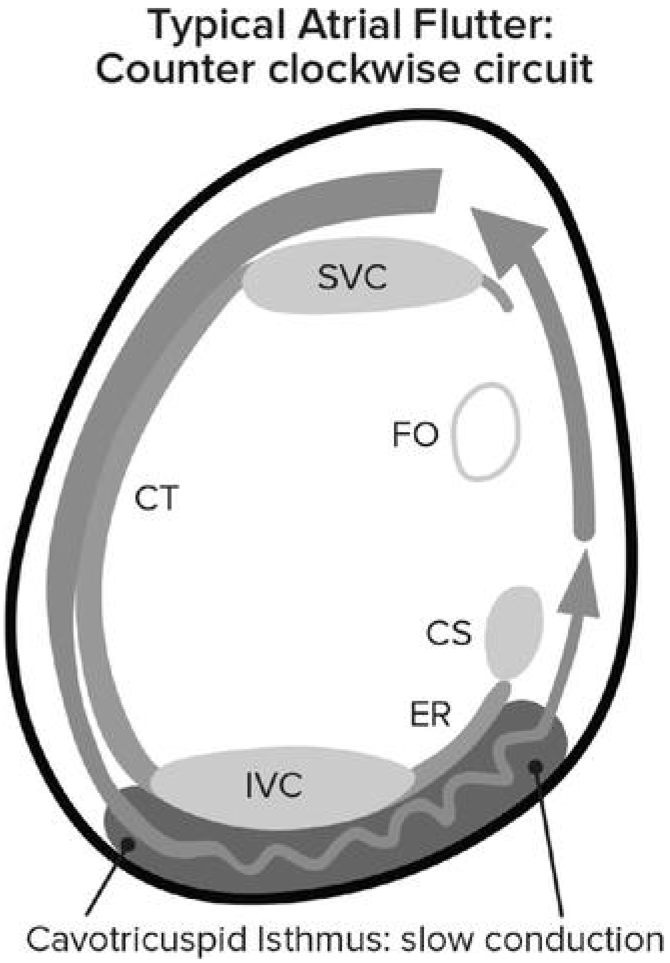
Box 31.3

Conditions associated with atrial flutter

Valvular heart disease
Post AF ablation
Myocardial infarction
Pericardial disease
Cardiac tumours
Hypertrophic cardiomyopathy
Congenital heart disease
Post surgical repair of congenital heart disease
Post cardiothoracic surgery
Post major non-cardiac surgery
Severe pulmonary disease
Pulmonary embolus
Thyrotoxicosis
Acute alcohol intoxication

AV conduction in Afl is usually 2:1, resulting in a regular rhythm, but conduction may be irregular. Rarely 1:1 AV conduction can occur and may be lethal.

Afl is classified according to the anatomical pathway of the circuit. Right atrial cavotricuspid-isthmus-dependent flutter involving a circuit bounded by tricuspid orifice, vena cavae orifices, Eustachian and crista terminalis, is overwhelmingly most common. From a left anterior oblique view (Fig. 31.19), this counterclockwise circuit makes up 90% of Afl cases and is classically referred to as ‘typical.’ Circuits can also be clockwise, involve the right atrium but with different circuits relating to scars or be located in the left atrium.



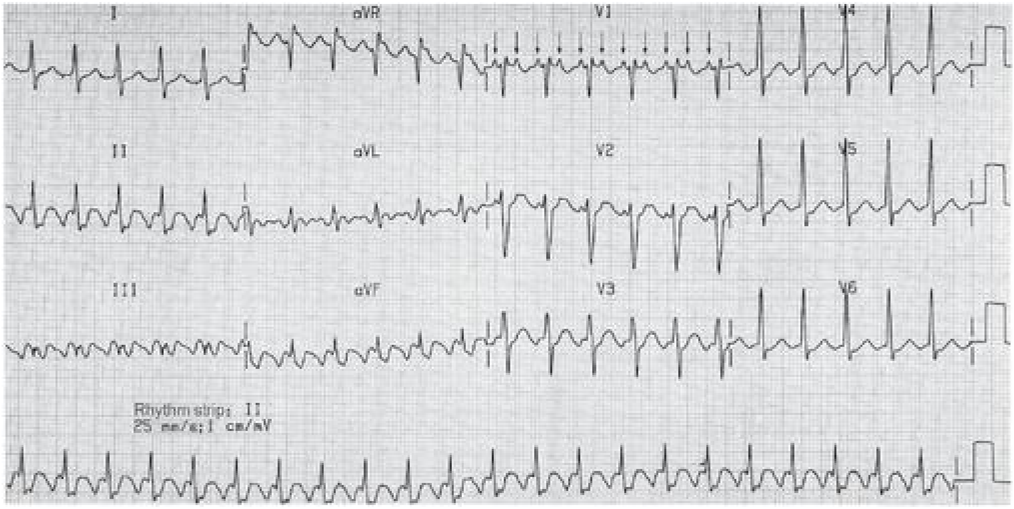
Typical Atrial Flutter:
Counter clockwise circuit
SVC
FO
CT
CS
ER
IVC
Cavotricuspid Isthmus: slow conduction

The illustration depicts a typical atrial flutter with a counter clockwise circuit. Key components include the superior vena cava S V C, inferior vena cava I V C, coronary sinus C S, foramen ovale F O, and cavotricuspid isthmus C T. The atrial flutter path is defined by these structures, with the electrical impulses circulating in a continuous loop, leading to rapid heartbeats. The illustration also highlights the electroanatomical regions involved, such as the right atrium and the surrounding areas critical for this arrhythmic condition.

FIG. 31.19 Right atrial cavotricuspid-isthmus-dependent atrial flutter. Circuit is confined by tricuspid annulus and internally bounded by superior and inferior vena cava (SVC, IVC), crista terminalis (CT), eustachian ridge (ER), coronary sinus (CS) and foramen ovale (FO).

ECG

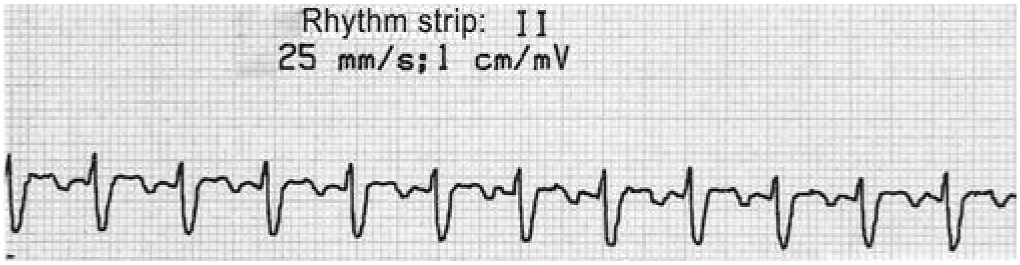
'Typical' Afl waves (characteristic sawtooth appearance with no isoelectric baseline) are best seen in V_1, and are negative in inferior leads with positive waves in V_1 that transition to negative in V_6 (Fig. 31.20). Rapid QRS waves may obscure typical flutter waves, and vagal manoeuvres may unmask them (see Fig. 31.9). AV conduction block (usually 2:1) is usually present, so that alternate flutter waves are conducted to the ventricles, with a ventricular rate close to 150 beats/min. Frequently flutter waves are not obvious and a ventricular rate of 150 beats/min leads to the presumption of Afl (Fig. 31.21). 'Atypical' Afl, normally associated with scar or structural abnormalities, often results in greater atrial and ventricular rates (Fig. 31.22). Treatment with drugs that affect AV node conduction may lead to higher degrees of AV block (Fig. 31.23) and/or variable AV block with irregular QRS duration. Afl with 1:1 conduction is associated with sympathetic overactivity, class I antiarrhythmic drugs (which slow atrial discharge rate to around 200 beats/min, thereby allowing each atrial impulse to be conducted) or WPW syndrome and a short antegrade refractory period of the accessory pathway (Fig. 31.24). QRS complexes are usually narrow, as conduction through the bundle branches is normal.



I
aVR
V1
V4
II
aVL
V2
V5
III
aVF
V3
V6
Rhythm strip: II
25 mm/s; 1 cm/mV

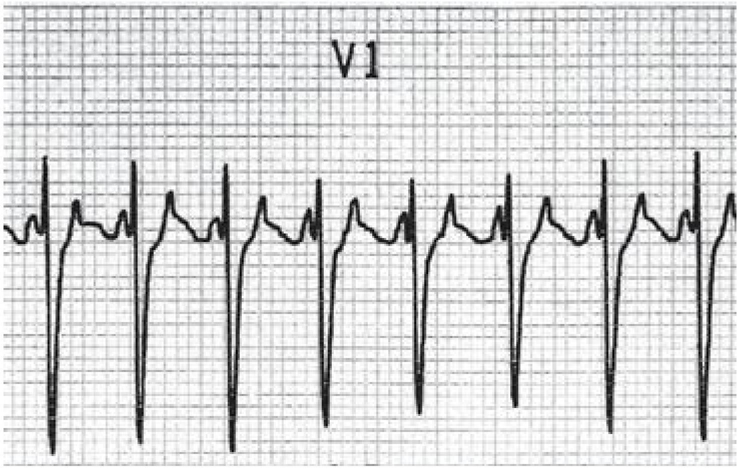
The E C G rhythm strip has different leads, including one, two, three, a V R, a V L, a V F, and V 1 to V 3. The strips display the heart's electrical activity, with varying waveforms and intervals representing P waves, Q R S complexes, and T waves. The leads are recorded from different angles of the heart.

FIG. 31.20 Atrial flutter with 2:1 atrioventricular conduction. Atrial rate is 270 beats/min (*arrows* V_1) and ventricular 135 beats/min. Characteristic ‘sawtooth’ inverted flutter waves are evident in leads II, III and aVF.



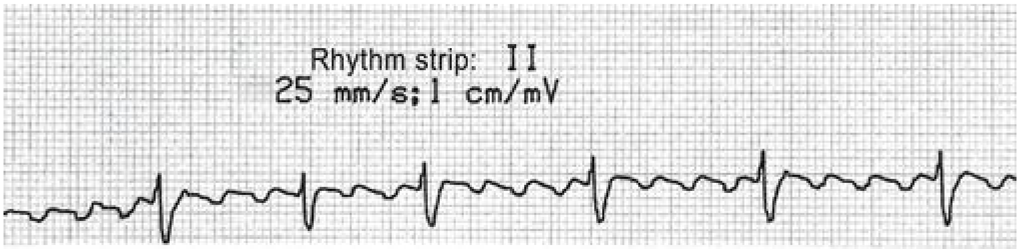
The E C G rhythm strip shows lead two, with a regular and consistent heart rhythm. The strip displays a series of repetitive P Q R S T complexes. The uniformity of the waves suggests a normal sinus rhythm without any visible abnormalities.

FIG. 31.21 Atrial flutter (Afl) with 2:1 atrioventricular (AV) conduction. Inverted flutter waves are difficult to differentiate from T-waves. Rate of 144 beats/min confirms Afl with 2:1 AV conduction.



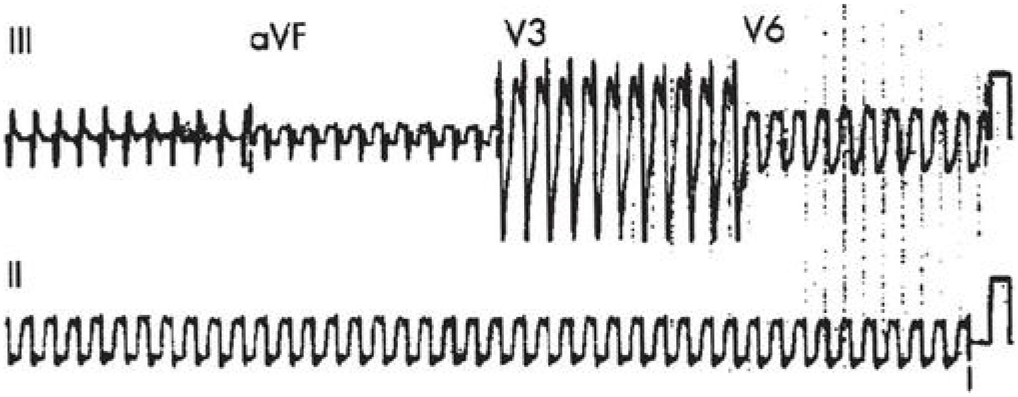
The E C G rhythm strip has lead V 1, showing a series of sharp, irregular Q R S complexes with distinct notching. The rhythm presents a regular pattern, but the Q R S complexes exhibit a characteristic appearance. The waveform features the typical V 1 configuration, reflecting the electrical activity of the right ventricle and related cardiac structures.

FIG. 31.22 Atrial flutter (Afl) with 2:1 atrioventricular conduction. Type II Afl is confirmed by the rapid atrial rate of 380 beats/min.



The E C G rhythm strip shows lead two. The rhythm presents irregular P Q R S T complexes. The appearance of the waves suggests the presence of an arrhythmia, possibly related to ectopic beats or irregular intervals between the P Q R S T complexes.

FIG. 31.23 Atrial flutter varying between 3:1 and 4:1 atrioventricular (AV) conduction due to drug effect slowing AV node conduction.



The E C G rhythm strip displays leads three, two, a V F, V 3, and V 6. The strip shows a rapid, irregular, and chaotic electrical activity. The other leads three, two, V 3, and V 6 display varying waveform patterns, with lead two exhibiting a regular rhythm.

FIG. 31.24 Atrial flutter with 1:1 conduction with a rate of 240 beats/min. Up-sloping of ST segment is easily mistaken as part of the QRS complex, giving the appearance of a broad QRS tachycardia in some leads. Lead III shows true narrow width of QRS complex.

Treatment [24, 30]

Drug therapy has proven to be notoriously unsuccessful for Afl and large doses of AV blockers are often needed for rate control. Although no drug will reliably terminate Afl, ibutilide and dofetilide have been shown to be most likely to result in pharmacological reversion. Flecainide and procainamide may also occasionally be effective at terminating Afl. Initial attempts at slowing ventricular rate by drugs that will increase the degree of AV block are worthwhile in the first instance. Drugs such as digoxin, diltiazem, beta-adrenergic blockers, sotalol and amiodarone may be tried; the choice depends on LV function. It is important to remember class IA and IC drugs may lead to 1:1 AV conduction. Class I drugs should probably be avoided unless ventricular response has been slowed with calcium channel or beta-adrenergic blocking drugs.

Synchronised DC cardioversion, often with low energies (25–50 J), is a reliable treatment option and is often required. Rapid atrial pacing faster than the flutter rate will terminate ‘typical’ Afl in most patients.

Anticoagulation guidelines are the same as those for AF, although there is less supporting data.

Prevention

Prevention is difficult. Drugs used include sotalol and amiodarone at low doses. Class IC agents (e.g. flecainide) may be used in patients without significant structural heart disease. Increasingly, recurrent or refractory Afl may be cured by radiofrequency ablation, which creates a linear lesion between the inferior tricuspid annulus and the Eustachian ridge at the anterior margin of the inferior vena cava to interrupt the re-entry circuit. [27] ‘Typical’ Afl is most amendable to circuit ablation.

Atrial Fibrillation [31, 32]

AF is the most common arrhythmia requiring treatment and/or hospital admission. The incidence increases with age: 5% of individuals over 70 years have this arrhythmia. There is also an age-independent increase in frequency owing to increasing obesity and obstructive sleep apnoea. LV dysfunction increases risk of AF (4.5-fold in men and 5.9 in women) with atrial stretch and fibrosis causing electrical and atrial ionic channel remodelling.

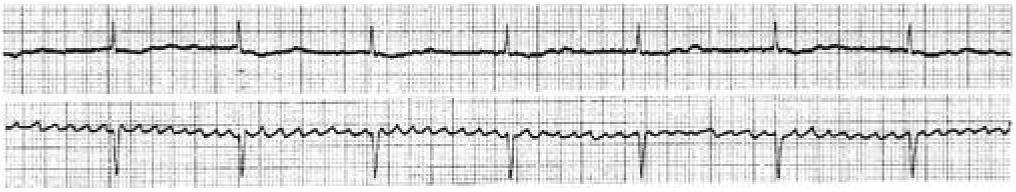
AF is common in:

- congestive cardiac failure (40%)
- coronary artery bypass grafting (CABG) (25%–50%)
- critically ill patients (15%).

Idiopathic or lone AF (i.e. with no structural heart disease or precipitating factor) in someone aged less than 60 years has an excellent prognosis; however, AF developing after cardiac surgery, for instance, is associated with increased stroke, life-threatening arrhythmias and longer hospital stays.

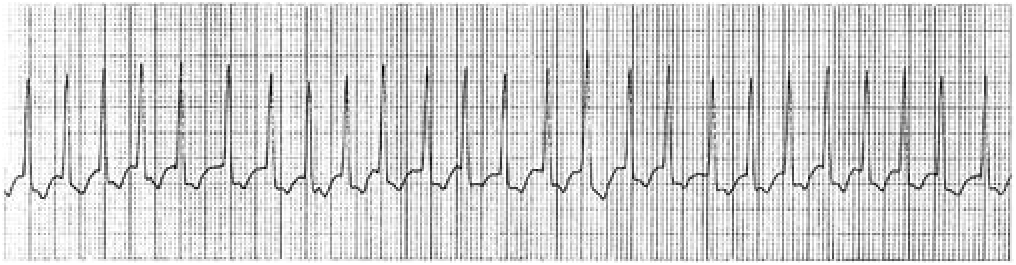
ECG

Atrial activity is chaotic with rapid (350–600 beats/min) and irregular depolarisation varying in amplitude and morphology (fibrillation waves). Ventricular response is irregularly irregular (Fig. 31.25). Most atrial impulses are not conducted to the ventricles, resulting in an untreated ventricular rate of 100–180 beats/min. QRS complexes will usually be narrow. When the ventricular rate is very rapid or very slow, ventricular irregularity may be missed (Fig. 31.26).



The E C G displays two segments with patterns. The top part shows a regular sinus rhythm with clear P Q R S T waveforms. The second part displays sinus arrhythmia, where the waveforms are irregular. The heart rate fluctuates in this segment, contrasting with the stable rhythm of the first segment.

FIG. 31.25 Atrial fibrillation. Irregular fibrillation waves with varying amplitude and morphology.



The E C G shows a pattern of consistent, sharp, and regular spikes that occur in a repetitive sequence. These spikes resemble a form of abnormal rhythm known as ventricular tachycardia, where the heart rate is faster than normal but regular in its occurrence. The intervals between each spike are similar, but there are small fluctuations visible in the wave amplitude.

FIG. 31.26 Atrial fibrillation with rapid ventricular rate. Ventricular irregularity and fibrillation waves are less evident when the rate is rapid.

Clinical

The variable terminology applied to AF has been clarified by the American Heart Association/American College of Cardiology/Heart Rhythm Society (AHA/ACC/HRS) Guidelines (Box 31.4). [32] AF is more common in patients with underlying heart disease (particularly those with a dilated left atrium) and abnormal atrial electrophysiology. Causes include ischaemic and valvular heart disease, pericarditis, hypertension, cardiac failure, thyrotoxicosis and alcohol abuse. AF may also occur after cardiac surgery and thoracotomy. AF can be chronic, or intermittent with paroxysmal attacks. Chronic AF has a poorer prognosis.

Box 31.4

Definitions of atrial fibrillation

Paroxysmal AF	AF that terminates with or without treatment within 7 days of onset
Persistent AF	Continuous AF sustained for more than 7 days
Long-standing AF	Continuous AF for greater than 12 months duration
Permanent AF	This term is used when the patient and clinician decide to stop further attempts to restore or maintain sinus rhythm

AF , Atrial fibrillation.

Adapted from January CT, Wann LS, Alpert JS. 2014 AHA/ACC/HRS Guideline for the management of patients with atrial fibrillation: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines and the Heart Rhythm Society. *Circulation.* 2014;130:2071–2104.

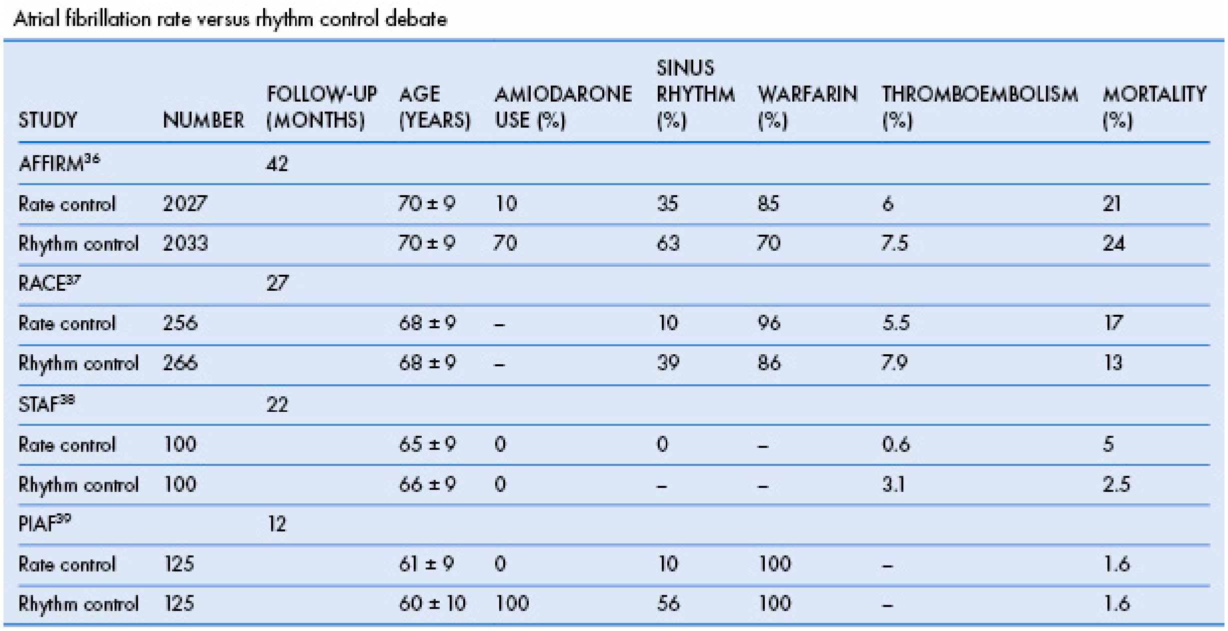
AF is associated with:

- *adverse haemodynamic effects:* rapid ventricular rate and loss of atrial systole may increase pulmonary capillary wedge pressure, while stroke volume and cardiac output decline
- systemic embolism and stroke
- *tachycardiomyopathy:* reversible global cardiomyopathy secondary to rapid heart rate. Assessing LV function with echocardiogram before and after AV node ablation for AF refractory to medical therapy suggests that 10% of patients with AF have AF-induced tachycardiomyopathy. [33]

Treatment [24, 34]

The goals of treatment include ventricular rate control, conversion to sinus rhythm, maintenance of sinus rhythm and anticoagulation where appropriate. Guidelines for the management of AF are multiple and extensive [32, 35] Evidence is evolving on the ‘rate versus rhythm’ control debate. Results from previous major trials challenged the belief that achievement of sinus rhythm is important in the long term (Table 31.5). When comparing control of ventricular rate versus reversion to sinus rhythm, no clear survival benefit was apparent. However, composite end-points of death, stroke and recurrent hospitalisation favoured rate control only. [36–39]

Table 31.5



Atrial fibrillation rate versus rhythm control debate

STUDY	NUMBER	FOLLOW-UP (MONTHS)	AGE (YEARS)	AMIODARONE USE (%)	SINUS RHYTHM (%)	WARFARIN (%)	THROMBOEMBOLISM (%)	MORTALITY (%)
AFFIRM[36]		42

STAF[38]		22						
Rate control	100		65 ± 9	0	0	–	0.6	5
Rhythm control	100		66 ± 9	0	–	–	3.1	2.5
PIAF[39]		12						
Rate control	125		61 ± 9	0	10	100	–	1.6
Rhythm control	125		60 ± 10	100	56	100	–	1.6

AFFIRM , Atrial fibrillation follow-up investigation of rhythm management; *PIAF* , Pharmacological Intervention in Atrial Fibrillation; *RACE* , rate control versus electrical cardioversion of persistent atrial fibrillation; *STAF* , strategies of treatment of atrial fibrillation.

The possible reasons why rhythm control was not been shown to be superior include:

- trials included predominantly elderly high-risk patients
- sinus rhythm was difficult to achieve (39%–63%)
- rate control strategies can result in sinus rhythm in up to 35% of patients
- underlying heart disease that initiates the AF persists
- there may be antiarrhythmic drug side effects
- anticoagulation is still required even if rhythm control is successful.

More recently, early rhythm control utilising antiarrhythmic drugs or ablation procedures in patients with pre-existing cardiovascular conditions demonstrated a significant reduction in risk of a composite outcome consisting of death from cardiovascular cause, stroke and hospitalisation with worsening heart failure or acute coronary syndrome.[40] Additionally, rhythm control (if possible) appears superior in patients with LV dysfunction, with both amiodarone and dofetilide reducing mortality when sinus rhythm is achieved.[36, 37, 41] The paucity of data in younger patients (less than 60 years) favours initial attempts at rhythm control, particularly in those with structurally normal hearts, in the hope that progressive atrial electrical and anatomical remodelling is prevented.

Recent Onset or Paroxysmal AF

Ventricular Rate Control (Table 31.6)

The urgency of ventricular rate control depends on the clinical situation and spontaneous reversion of AF is common. Treatment may not be necessary, and a reasonable strategy is based on clinical status:

- Haemodynamically unstable with rapid ventricular rate requires immediate synchronised DC shock (in addition to drug therapy) to control rate urgently.
- Haemodynamically stable, symptomatic with depressed LV function: semi-urgent synchronised DC shock or drug therapy,

digoxin or amiodarone to control ventricular rate.

- Haemodynamically stable, symptomatic, normal LV function: control of ventricular response with beta-adrenergic blockers, diltiazem, digoxin (digoxin has poor control with exertion and other settings with increased sympathetic tone), magnesium (short term), amiodarone or sotalol.
- Haemodynamically stable, with no structural heart disease and minimal or no symptoms: no immediate treatment is an option. Most cases will revert spontaneously within 24 hours. Single-dose flecainide for paroxysmal AF has been recommended (contraindicated in patients with structural heart disease). [32]
- If pre-excitation is suspected, beta-adrenergic blockers, non-dihydropyridine calcium channel antagonists, digoxin and adenosine are contraindicated. Class I drugs are indicated. Amiodarone is no longer recommended (see Pre-excitation syndrome).

Table 31.6

Drugs for ventricular rate control in atrial fibrillation

	ACUTE	CHRONIC
STABLE	BETA BLOCKERS	
	Metoprolol 2.5–5 mg IV bolus over 2 min – up to 3 doses Esmolol 50–200 μg/kg/min IV	Metoprolol ER 100–200 mg oral daily Atenolol 25–100 mg oral daily Bisoprolol 2.5–10 mg oral daily
	NON- DIHYDROPYRIDINE CALCIUM CHANNEL ANTAGONISTS	Verapamil 40 mg oral b.d. up to 360 mg ER oral daily Diltiazem 60 mg oral t.i.d. up to 360 mg ER oral daily
	Verapamil 0.0375–0.15 mg/kg IV over 2 min	
UNSTABLE: HYPOTENSION HEART FAILURE	Digoxin 0.5–1.0 mg IV Amiodarone 5 mg/kg IV over 1 h	Digoxin 0.125–0.50 mg oral daily Amiodarone 100–200 mg oral daily

ACUTE		CHRONIC
		Dronedarone 400 mg oral b.d.

Ideal rate control can be defined as a resting heart rate of ≤80 beats/min, peak rate of ≤110 beats/min with a 6-minute walk and an average of 100 beats/min.

Conversion to Sinus Rhythm

Antiarrhythmic drugs or DC shock cardioversion can be used. The likelihood of short- and long-term success depends on the clinical situation. Conversion to sinus rhythm is more important in young patients and those with heart failure. Maintenance of sinus rhythm is problematic: sinus rhythm at 1 year is 60% with amiodarone and 40% with sotalol and is associated with significant drug cardiac and extracardiac toxicities. The risk of stroke and need for antithrombotic therapy due to frequent AF recurrences, which may be asymptomatic, remain.

Pharmacological conversion of recent-onset AF is variously successful depending on the clinical setting and agent used (Table 31.7). Ibutilide, propafenone and vernakalant have rapid conversion rates, compared with flecainide and amiodarone the slowest. Amiodarone, ibutilide and vernakalent are suitable in heart failure. All have risk of QT prolongation and proarrhythmia, with ibutilide being the worst and vernakalant the best, although there are anecdotal case reports of ventricular arrhythmias with the latter.[42–44]

Table 31.7

Drugs for pharmacological conversion of recent-onset atrial fibrillation

DRUG	DOSE	FEATURES
Amiodarone	5 mg/kg IV over 1 h	Will slow ventricular rate Conversion delayed Amiodarone 80%–90%, placebo 40%–60% at 24 h Suitable structural heart disease and heart failure
Flecainide	2 mg/kg IV over 10 min 200–300 mg oral	Not suitable for structural heart disease or heart failure 67%–92% conversion at 6 h Majority within 1 h of IV dose May prolong QT Risk of Afl and 1:1 conduction
Ibutilide	1 mg IV over 10 min Further dose after 10 min	50% conversion within 90 min Risk of QT prolongation and torsades de points high
Propafenone	2 mg/kg IV over 10 min	Not suitable for structural heart disease or heart failure 41%–91% conversion within 3 h May prolong QT Risk of Afl and 1:1 conduction
Vernakalant	3 mg/kg IV over 10 min Further, 2 mg/kg if required	Suitable for structural heart disease and heart failure Rapid in approximately 10 min in responders 50% conversion rate

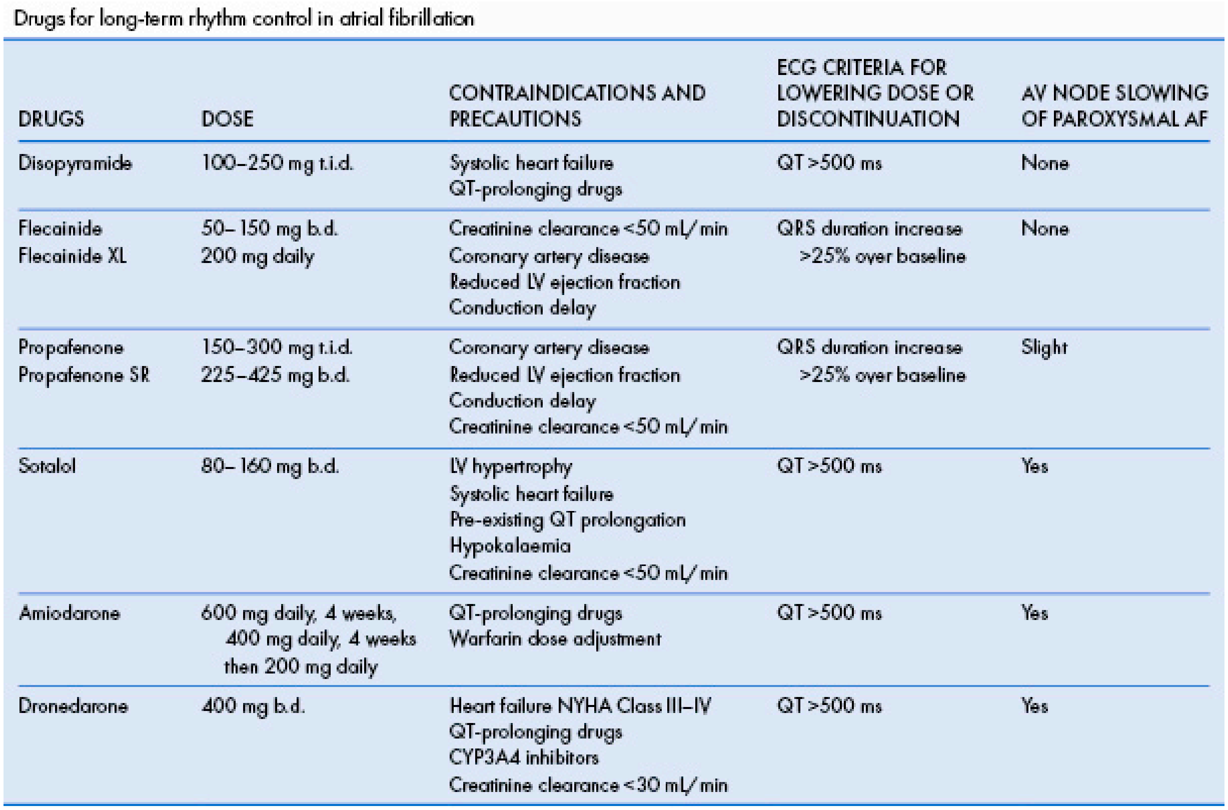
DRUG	DOSE	FEATURES
		99% of responders remain in sinus rhythm at 24 h after a single dose Well tolerated

---

Afl , Atrial flutter.

All antiarrhythmic drugs have contraindications and precautions (Table 31.8), with amiodarone the best from a cardiac perspective and worst from an extracardiac point of view. The dilemma of long-term antiarrhythmic treatment in AF is highlighted by the diametrically opposite effects that dronedarone has been shown to produce in this setting. [45] In ATHENA, dronedarone decreased all cause, cardiovascular and presumed arrhythmia mortality, stroke and heart failure, whereas in PALLAS all these outcomes were worse. In PALLAS, all patients had ‘permanent’ AF and there was twice the baseline incidence of heart failure. Benefit would appear to be crucially dependent upon securing sinus rhythm, absence of structural substrate for proarrhythmia and cardiac reserve to tolerate the drug.

Table 31.8



Drugs for long-term rhythm control in atrial fibrillation

DRUGS	DOSE	CONTRAINDICATIONS AND PRECAUTIONS	ECG CRITERIA FOR LOWERING DOSE OR DISCONTINUATION	AV NODE SLOWING OF PAROXYSMAL AF
Disopyramide	100–250 mg t.i.d.	Systolic heart failure QT-prolonging drugs	QT >500 ms	None
Flecainide Flecainide XL	50–150 mg b.d. 200 mg daily	Creatinine clearance <50 mL/min Coronary artery disease Reduced LV ejection fraction Conduction delay	QRS duration increase >25% over baseline	None
Propafenone Propafenone SR	150–300 mg t.i.d. 225–425 mg b.d.	Coronary artery disease Reduced LV ejection fraction Conduction delay Creatinine clearance <50 mL/min	QRS duration increase >25% over baseline	Slight
Sotalol	80–160 mg b.d.	LV hypertrophy Systolic heart failure Pre-existing QT prolongation Hypokalaemia Creatinine clearance <50 mL/min	QT >500 ms	Yes
Amiodarone	600 mg daily, 4 weeks, 400 mg daily, 4 weeks then 200 mg daily	QT-prolonging drugs Warfarin dose adjustment	QT >500 ms	Yes
Dronedarone	400 mg b.d.	Heart failure NYHA Class III–IV QT-prolonging drugs CYP3A4 inhibitors Creatinine clearance <30 mL/min	QT >500 ms	Yes

DC Shock Cardioversion

DC shock cardioversion is indicated either before 24–48 hours or after appropriate anticoagulation protocol. Combining DC shock with antiarrhythmic drugs to promote maintenance of sinus rhythm is favoured, especially if risk factors for relapse exist. Cardioversion is less likely to be successful if:

- AF has been present for over 1 year
- left atrial size is greater than 45 mm
- untreated conditions are present (e.g. thyrotoxicosis, valvular heart disease and heart failure).

Critically ill patients who are septic, postoperative or on drugs such as catecholamines are likely to relapse.

Anticoagulation and Cardioversion [46, 47]

Loss of atrial contraction with AF is associated with stasis of blood flow and the formation of blood clots in the left atrium, particularly the atrial appendage. Reversion to sinus rhythm and return of more effective atrial contraction may cause expulsion of any atrial clots and systemic emboli. Once AF has been present for more than 48 hours – some authors stipulate 24 hours – the risk of systemic emboli is significant and anticoagulation is required prior to DC shock cardioversion. The current recommended period of anticoagulation prior to DC shock cardioversion is 3 weeks. This 3-week period can be shortened to 1 day for heparin and 5 days for warfarin if the left atrium can be demonstrated free of clot using transoesophageal echocardiography. With this accelerated approach, heparin dose should be titrated to an activated partial thromboplastin time 2–3 times control or warfarin to produce an international normalised ratio (INR) of 2.0–3.0. In many clinical situations such as recent surgery or other bleeding risks, anticoagulation is contraindicated and elective cardioversion should be delayed until recommended anticoagulation cover is safe. Following successful cardioversion to sinus rhythm, the risk of systemic embolism continues as the propensity to form atrial clot remains owing to atrial contractile stunning and anticoagulation should be continued for 4–6 weeks.

Atrial Fibrillation Ablation Therapy

Ablation techniques for AF have been continuously refined since the original Maze III surgical procedure, which involved numerous atrial incisions to form a maze-like pattern of scarring, blocking propagation of arrhythmia. The utility of this procedure was limited because it was surgical, associated with longer bypass times, more postoperative bleeding and impaired atrial contractility. The magnitude of this original procedure was based on the belief that the entire atrium was involved in the initiation and maintenance of fibrillatory conduction. This may be true for long-standing AF but paroxysmal AF appears to originate primarily at the junction of the left atrium and pulmonary veins. AF in 94% of patients is initiated by rapid discharges from one or more foci at or near the pulmonary vein orifices. [48] Atrial tissue in this area has heterogeneous electrophysiological properties and there is also clustering of vagal inputs, which creates substrate for rapid discharges that initiate micro-re-entrant circuits or ‘rotors.’ These high-frequency periodic rotors send spiral wavefronts of activation into surrounding atria. Localised ablation of a single dominant focus and rotor is inadequate, as there are usually multiple foci. Surgical excision of left atrial appendage may also be considered.

AF radiofrequency or cryoablation is being utilised more extensively with increasing evidence to support its use. Results are improving, as all pulmonary veins are now isolated and the encircling lesion is clear of the pulmonary vein antrum (reducing pulmonary vein stenosis). Recently, more extensive ablation is advocated and in addition to pulmonary vein isolation, the entire left atrial posterior wall and superior vena cava are isolated as well, especially if pulmonary vein-like potentials are found. Success rates of 81% (75%–88%) free of AF and off drugs are reported. Success appears long term as any recurrence occurs early. A further 10%–20% may become responsive to antiarrhythmic drugs which were previously ineffective. Repeating the procedure can increase success to >90%, with failure only in patients found to have extensive atrial scarring (predicting and excluding patients with this extensive atrial scarring is a major future challenge). Cryoablation has similar rates of overall safety and efficacy as opposed to radiofrequency ablation with benefits of reduced complexity and procedure duration, at the expense of increased fluoroscopy exposure and phrenic nerve injury [49]

Complications include:

- TIA, stroke
- Perforation – tamponade, oesophageal injury
- Pulmonary oedema – early from high rates of saline administration, late from pulmonary vein stenosis
- Recurrent AF
- Difficult to treat Afl

Proarrhythmia commonly results from re-entrant tachycardia from incomplete ablative lesions. Complication rates are falling with experience, intracardiac echocardiography ensuring safer transseptal puncture and positioning of isolating lesions clear of the pulmonary vein antra, procedural anticoagulation and limitations on radiofrequency energy output.

Ablation may now be considered first-line treatment, as opposed to limiting utilisation where rhythm control with antiarrhythmic drugs has failed. Successful rhythm control is superior with ablation with reduced side effects compared with antiarrhythmic drugs. Early non-randomised studies comparing ablation and antiarrhythmic drugs suggest superior outcomes in the setting of heart failure, survival benefit, improved quality of life, reduced adverse effects and cost-effectiveness after approximately 3 years with catheter AF ablation therapy. [50-53] Subsequent randomised trials have added further support to consider ablation as first-line therapy for rhythm control in selected patients with paroxysmal AF with lower rates of persistent or recurrent atrial tachyarrhythmia, hospitalisation and adverse effects compared with antiarrhythmic drugs. [54]

There is renewed interest in surgical AF ablation therapy in conjunction with cardiac surgery. Complications have been reduced with energy (cryotherapy, radiofrequency) rather than incisions and the extent of lesions reduced. The minimum lesion set is now considered to be encirclement of pulmonary veins, linear lesion from the inferior pulmonary vein to mitral annulus and from the coronary sinus to the inferior vena cava.

AF and Structural Heart Disease

The onset of AF, especially with rapid ventricular rates, often precipitates haemodynamic collapse requiring immediate control with DC shock in structural heart disease. Valvular and myopathic heart disease demands prompt preventive ablation or antiarrhythmic drugs to secure sinus rhythm.

- AF in hypertrophic cardiomyopathy (HCM). [55]

AF incidence is 4–6 times greater (18%–28%) due to left atrial dilation and remodelling due to diastolic dysfunction, increase in left ventricular end diastolic pressure, primary sarcomeric atrial myopathy, left ventricular outflow tract obstruction (LVOTO) and mitral regurgitation.

AF results in a fourfold increase in HCM all-cause mortality.

Significance mandates 24–48 hours of ambulatory monitoring every 6–12 months, especially if left atrium is greater than 45 mm. Highly sensitive troponin T predicts death and AF.

Stroke and systemic emboli are eightfold more likely than in the general population AF – risk so high that CHA_2DS_2-VAScscore is not used. All are anticoagulated after one episode.

While in many settings of superiority of rhythm versus rate control continues. However, with significant LVOTO, AF is so poorly tolerated that rhythm control is superior. Amiodarone is most effective to maintain sinus rhythm but long-term side effects. Disopyramide is recommended as negative inotropic action relieves symptomatic LVOTO. Must be used with AV-blocking agent (beta-blocker, diltiazem or verapamil) to prevent rapid ventricular rates during AF episodes. Disopyramide dose must be decreased or ceased if QTc is greater than 480 ms. Otherwise monotherapy with sotalol.

AF ablation is indicated for failed medical treatment although less successful than with lone AF.

If surgical myectomy is required, a Maze procedure and left atrial appendage excision should be performed.

Anticoagulation for Chronic Atrial Fibrillation

[32], [35]

Valvular Atrial Fibrillation

A 17-fold increased risk of embolic stroke with rheumatic mitral valve disease requires warfarin (INR 2–3). With prosthetic valves, there is a similar target range of INR, though the exact level is dependent on the type of valve.

Non-Valvular Atrial Fibrillation

The risk of stroke has been determined by the $CHADS_2$ score (assign 1 point for congestive heart failure, hypertension, age ≥ 75 years and diabetes mellitus and 2 points for stroke/TIA).[56] The $CHADS_2$ score has been further developed to the CHA_2DS_2 VASc score to improve risk stratification of patients at moderate risk by doubling points to 2 for age ≥75 and including vascular disease (prior myocardial infarction, peripheral artery disease determined by prior revascularisation, amputation or angiographic evidence and aortic plaque, age 65–74 and female sex) (Table 31.9).

Table 31.9

[a] Based on Lip GY, Frison L, Halperin JL, Lane DA. Identifying patients at high risk for stroke despite anticoagulation: a comparison of contemporary stroke risk stratification schemes in an anticoagulated atrial fibrillation cohort. *Stroke* 2010;41(12):2731–2738.

TIA , Transient ischaemic attack.

The treatment options are discussed below.

Warfarin

Adjusted-dose warfarin reduces relative risk of stroke by 62%. The absolute risk reduction is 2.8% per year for primary and 8.4% per year for secondary prevention, although intracranial haemorrhage occurs (0.3% per year). Low-dose warfarin (INR 1.5–2.0) is less effective than an INR of 2.0–3.0 but has fewer haemorrhagic complications. Embolic stroke rate doubles as INR falls from 2.0 to 1.7, and is markedly higher at an INR of 1.3 compared with 2.0. [46, 57]

Aspirin

Aspirin has reduced efficacy when compared with warfarin, with a 22% relative risk reduction and an absolute risk reduction of 1.5% and 2.5% per year for primary and secondary prevention. Warfarin compared with aspirin for AF will prevent 23 strokes and result in nine additional major bleeds per 1000 patients per year.

Clopidogrel Plus Aspirin

Although warfarin is better under ideal circumstances with regards to prevention of stroke, systemic embolism, myocardial infarction and vascular death, poor INR control will readily erode this benefit.

Warfarin Combined With Antiplatelet Therapy

There is no benefit over warfarin alone, with associated increased risk of major bleeding.

Non-vitamin-K-antagonist Oral Anticoagulants (NOACs) (Box 31.5)

NOACs have an increasing role in AF anticoagulation with the benefit of fixed dosing not requiring monitoring. The evidence for superiority in non-valvular AF is oldest for dabigatran; however, other NOACs have the benefit of once-daily dosing (Rivaroxaban) and use in moderate renal failure (Apixaban). In non-valvular AF, dabigatran 150 mg b.d. had a 35% reduction in stroke and systemic embolism compared with warfarin. There was a similar rate of major bleeding, although intracranial haemorrhage was reduced by 59%. The lower dose of 110 mg b.d. had similar embolic efficacy to warfarin but with reduced bleeding. Dabigatran clearance is importantly influenced by creatinine clearance of less than 50 mL/min. Apixaban (ARISTOTLE) was superior to warfarin due to reduction in haemorrhagic strokes and ischaemic strokes with haemorrhagic conversion. Rivaroxaban was non-inferior to warfarin (ROCKET-AF). Reversal agents exist for the NOACs; idarucizumab (dabigatran) and andexanet alfa (factor Xa inhibitors).

Box 31.5

Non-vitamin-K-antagonist oral anticoagulants

Dabigatran

Direct thrombin inhibitor

150 mg oral b.d.
Age ≥75 years, Creatinine clearance <50 mL/min decrease dose 110 mg oral b.d.
CrCl <30 mL/min contraindicated

Rivaroxaban

Factor Xa inhibitor

20 mg oral daily
CrCl <50 mL/min decrease dose 15 mg oral daily

Apixaban

CrCl <30 mL/min contraindicated

Factor Xa inhibitor
5 mg oral b.d.
Age ≥80 years, <60 kg or CrCl <50 mL/min decrease dose 2.5 mg oral b.d.

Recommendations for Anticoagulation in Patients With Atrial Fibrillation

Non-Valvular Atrial Fibrillation

INR adjusted warfarin (2.0–3.0 target 2.5) or aspirin according to CHA$_2$DS$_2$VASc score and HAS-BLED score (Tables 31.10 and 31.11).

Table 31.10

Approach to thromboprophylaxis in patients with atrial fibrillation

CHA$_2$DS$_2$VASc SCORE	**RECOMMENDED ANTITHROMBOTIC THERAPY**
≥2	Oral anticoagulation –warfarin international normalised ratio (INR) 2.0–3.0 Target 2.5 –dabigatran –HAS-BLED score ≥3: dabigatran 150 mg b.d. <3: dabigatran 110 mg b.d.
1	Either oral anticoagulant –warfarin INR 2.0–3.0 Target 2.5 –dabigatran 110 mg b.d., *or* –aspirin 75–325 mg daily Prefer oral anticoagulation rather than aspirin
0	Either aspirin 75–325 mg daily, *or* No antithrombotic therapy Prefer no antithrombotic therapy rather than aspirin

Table 31.11

INRs , International normalised ratios.

NOACs may be substituted for warfarin, depending on risk of bleeding. Risk of bleeding can be determined by the HAS-BLED score. With a HAS-BLED score of 0–2, dabigatran 150 mg b.d. gives superior embolic prevention with reduced intracranial haemorrhage. With a HAS-BLED score of ≥3, 110 mg b.d. gives similar efficacy to warfarin, but reduced haemorrhagic complications.

Valvular Atrial Fibrillation

Warfarin is indicated in patients with rheumatic mitral stenosis and mechanical heart valves. NOACs may be considered in patients with bioprosthetic valves (>3 months post-implantation) or other native valvular heart disease (excluding rheumatic mitral stenosis). [58] Risk of haemorrhage is reduced by keeping INR = 3, systolic blood pressure <135 mm Hg and avoiding antiplatelet drugs.

Temporary cessation of anticoagulation for AF with surgery is a common problem. Valvular AF requires heparin or enoxaparin until surgery and recommencement of heparin/enoxaparin, then warfarin as soon as safely possible. Non-valvular CHA_2DS_2VASc score <2 can have anticoagulation withheld with minimal risk. Non-valvular CHA_2DS_2VASc score of ≥2 is increasingly managed as valvular AF.

Angioplasty and stenting of coronary arteries require aspirin and clopidogrel to maintain stent patency. Stenting in patients already on warfarin for AF is a common problem.

Recommendations for Atrial Fibrillation Patients Requiring Coronary Artery Stenting

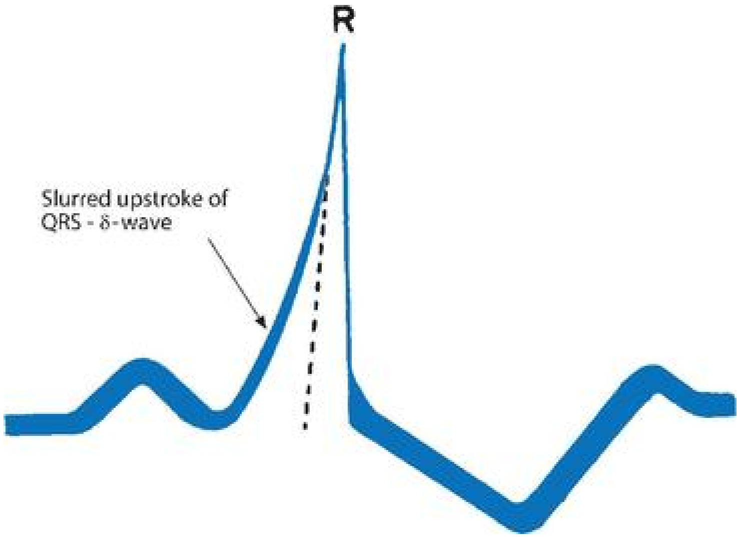
- Non-valvular CHA_2DS_2VASc score <2: cease warfarin as aspirin and clopidogrel are started.
- Valvular AF and non-valvular with CHA_2DS_2VASc score ≥2: add aspirin and clopidogrel to continued warfarin treatment. Continuation of triple antithrombotic therapy beyond the initial high-risk period for in-stent thrombosis, as opposed to dual thrombotic therapy (i.e. oral anticoagulant and single antiplatelet), should be individualised taking into account thrombotic and bleeding risk.

Pre-Excitation Syndrome

Pre-excitation syndromes have an additional or accessory AV pathway. The term ‘WPW syndrome’ is usually applied when tachyarrhythmia is present.

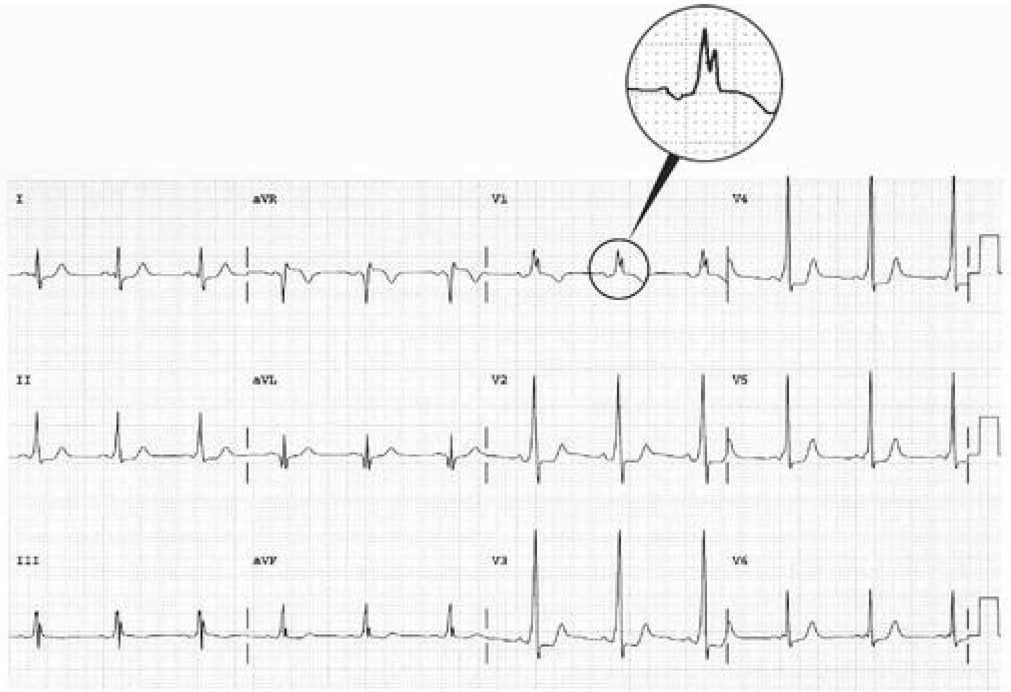
ECG

During sinus rhythm, an atrial impulse will reach the ventricles via both the AV node and the accessory AV pathway. The latter conducts the atrial impulse to the ventricles before the AV node, resulting in ventricular pre-excitation and a short PR interval. On reaching the ventricles, the pre-excitation impulse is not conducted via the specialised conducting system. Hence, early ventricular activation will be slowed, resulting in a slurred upstroke of the QRS complex, the so-called delta (δ) wave (Fig. 31.27). The abnormal ventricular activation also gives rise to secondary S-T segment and T-wave abnormalities; δ-wave polarity in a 12-lead ECG may help localise the anatomical position of the accessory pathway. Type A WPW is characterised by upright QRS deflections in the right precordial leads (tall R-waves in V_1 and V_2) (Fig. 31.28). In type A WPW, the accessory pathway is usually situated on the left with pre-excitation of the left ventricle. Type B WPW has a dominantly negative QRS complex in V_1 and the accessory pathway tends to be on the right with pre-excitation of the right ventricle (Fig. 31.29).



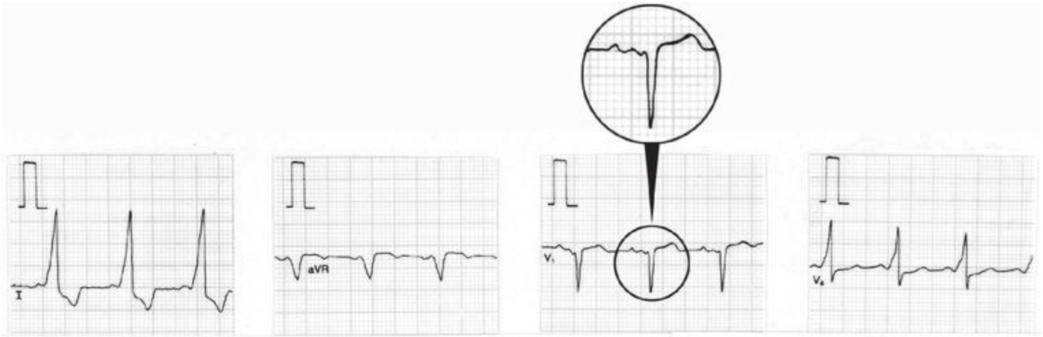
This illustration shows a portion of an electrocardiogram waveform, highlighting a slurred upstroke in the Q R S complex, which is identified as a delta wave. The sharp R wave is also marked in the diagram. The delta wave causes a prolonged Q R S interval. The slurring of the upstroke distinguishes it from the normal sharp Q R S complex seen in typical E C G.

FIG. 31.27 Ventricular pre-excitation via accessory pathway giving rise to a slurred upstroke and widened QRS complex.



The E C G presents three different leads one, two, and three. A magnified section of the E C G highlights a large, sharp spike in one of the leads, which stands out as a potential abnormality. In the other leads, the waveforms appear more regular, though some irregularities may still be present. The magnified section offers a closer look at the abnormal spike.

FIG. 31.28 Type A Wolff–Parkinson–White syndrome with positive R-waves in the right precordial leads, short PR interval and δ-wave giving rise to a wide QRS complex.

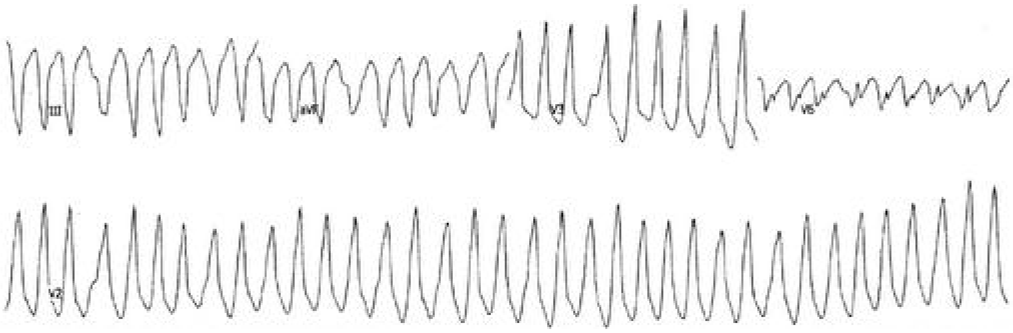


The E C G shows leads one, two, three, and A V R, with a focus on a marked abnormality in the lead labelled A V R. The magnified section reveals a deep, sharp deflection in the waveform. The other leads show less pronounced abnormalities, suggesting that the issue may be isolated to the area shown in the magnified portion.

FIG. 31.29 Type B Wolff–Parkinson–White syndrome with a negative QRS deflection in V_1 .

Clinical

AVRT or AF can occur with WPW. During AVRT, the re-entry impulse usually travels down the AV node and back up the accessory pathway. Ventricular activation is via the normal conducting pathways and the QRS will be narrow. Occasionally, the re-entry impulse may pass in the opposite direction (down the accessory pathway and up the AV node), resulting in a wide QRS-complex tachycardia due to abnormal slow ventricular activation. Treatment is the same as for AVRT (i.e. intravenous [IV] adenosine). AF is uncommon in WPW but may be life threatening. Most impulses are conducted via the accessory pathway, leading to wide QRS complexes. The ECG of WPW with AF usually shows rapid, irregular QRS complexes with variable QRS width (Fig. 31.30).



The E C G displays two segments of an electrocardiogram, both showing rapid, irregular oscillations in the waveform. The top segment depicts a pattern of erratic, sharp spikes and dips, while the bottom segment presents a more consistent but still rapid series of oscillations.

FIG. 31.30 Wolff–Parkinson–White syndrome with atrial fibrillation. Rapid rate and irregularity of the broad QRS complexes help to distinguish from ventricular tachycardia.

Ventricular response is very rapid, leading to hypotension or cardiogenic shock. This arrhythmia may degenerate to VF.

Treatment [24]

Treatment usually involves synchronised DC shock if haemodynamically compromised. Antiarrhythmic drugs may be used when patients are haemodynamically stable and the ventricular rate is not excessively rapid.

- Ideal agent needs predominant action of prolonging refractory period of accessory pathway.

Agents with predominant action of slowing AV node can increase conduction rate through the accessory pathway and cause life-threatening rapid ventricular rates in the setting of AF.

Intravenous procainamide or Ibutilide has best profile.

Amiodarone and flecainide have been used but are not ideal due to strong AV-blocking action even though they slow accessory pathway conduction.

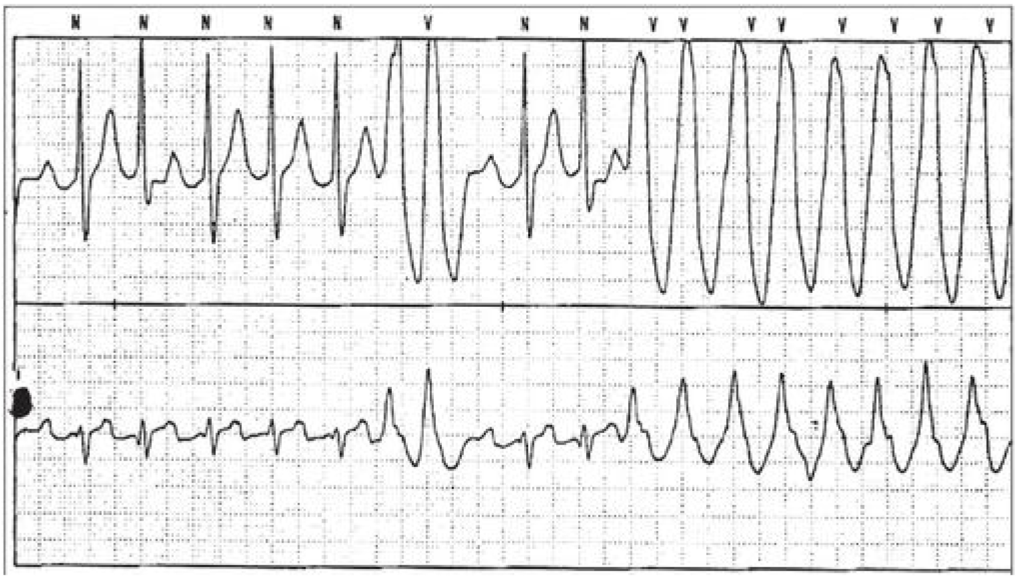
Digoxin is greater than 130 beats/min contraindicated as blocks AV node and increases accessory pathway conduction by shortening refractory period.

Non-dihydropyridine calcium channel blockers and adenosine may be harmful by increasing ventricular rate by blocking the AV node.

Long-term management by radiofrequency ablation of the accessory pathway is effective in selected patients.

Ventricular Tachycardia

VT is defined as three or more VEBs at a rate greater than 130 beats/min and may exceed 300 beats/min. VT lasting over 30 seconds is considered to be sustained. Non-sustained VT may not cause symptoms but is associated with increased mortality in certain patients (e.g. after myocardial infarction). VT may be monomorphic (i.e. the same QRS morphology) (Fig. 31.31) or polymorphic (varying QRS morphology).

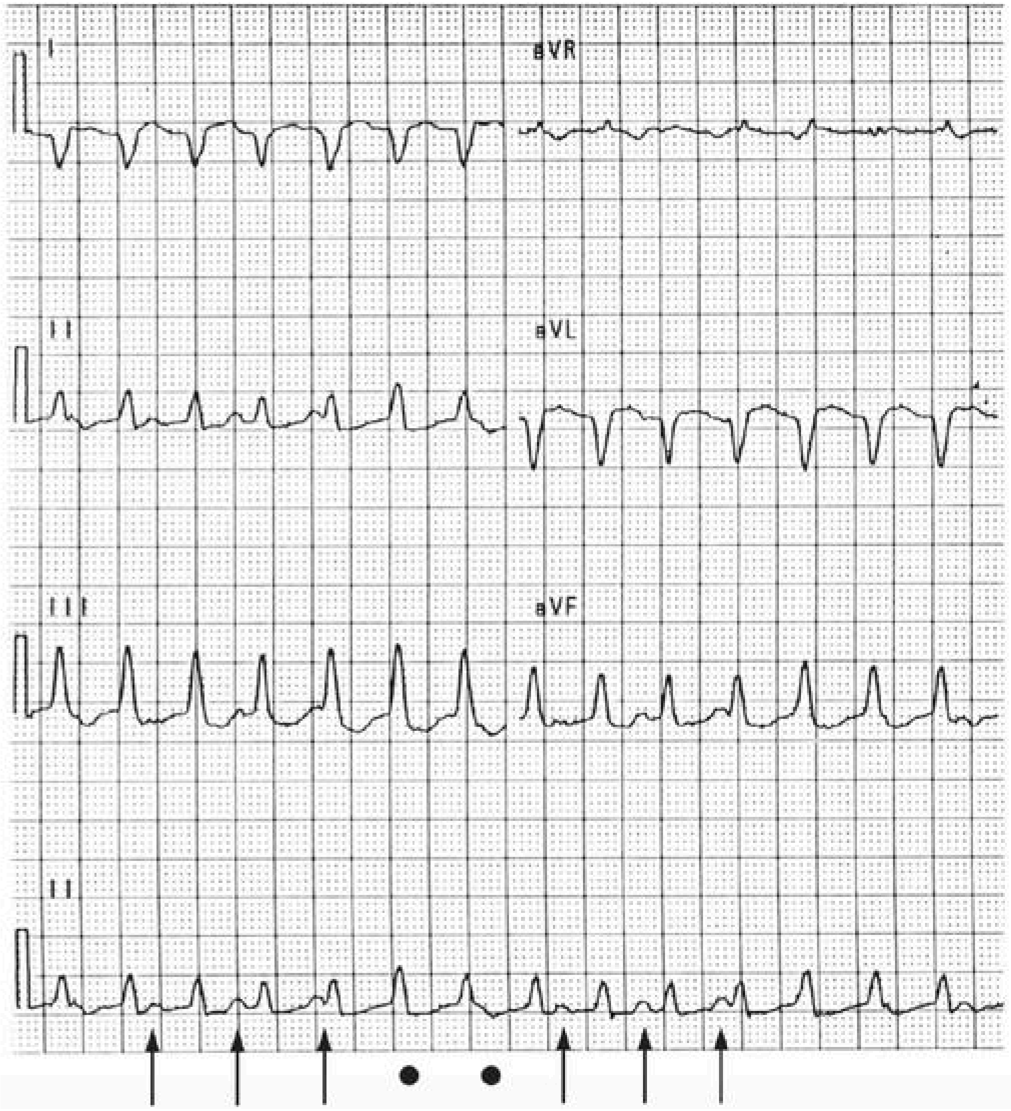


The E C G contains two segments. The upper segment depicts an abnormal rhythm with alternate waveforms, while the lower segment features a normal, consistent rhythm with clear P Q R S T waves. The consistent rhythm in the lower segment confirms a normal heart function, providing a clear contrast to the irregularities above.

FIG. 31.31 Monomorphic ventricular tachycardia preceded by a ventricular couplet.

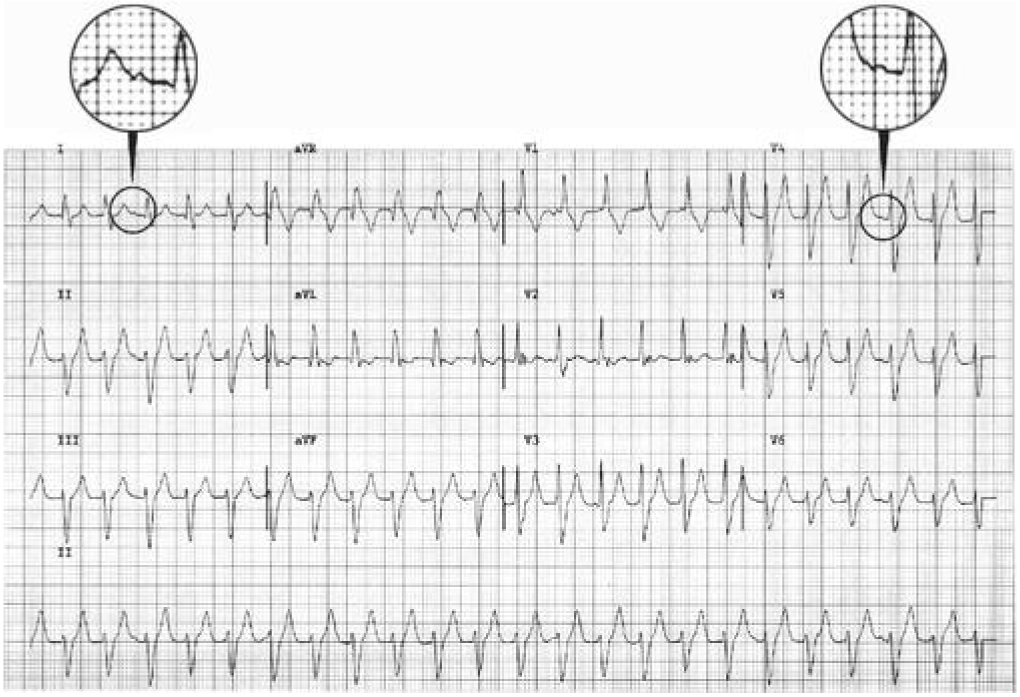
Monomorphic Ventricular Tachycardia

This is the most common form of VT. It is commonly associated with previous myocardial infarction and often causes symptoms (e.g. palpitations, shortness of breath and chest pain or syncope). It may result in cardiac arrest due to the tachycardia itself or degeneration into VF. The most common mechanism is re-entry secondary to inhomogeneous activation of the myocardium and slow conduction through scar tissue from a previous myocardial infarction. AV dissociation (i.e. independent atrial and ventricular activity) (Fig. 31.32) is present in about 75% of instances, whereas retrograde ventricle-to-atrial conduction occurs in about 25%. AV dissociation is virtually diagnostic for VT during a wide-complex tachycardia, but ECG recognition of independent (and slower) atrial activity can be difficult (Fig. 31.33). VT is the most common cause of a wide-complex tachycardia (QRS >120 ms) and any such tachycardia should be considered VT until proven otherwise. Mistakes in diagnosis are common: SVT with aberrant conduction is often mistaken for VT. Inappropriate treatment based on incorrect diagnosis can have disastrous consequences.



The twelve-lead electrocardiogram presents six limb leads labelled from top to bottom as a V R, a V L, a V F, one, two, and three. Each lead displays a regular rhythm composed of rapid, narrow Q R S complexes that occur at a high frequency. There are no distinct P waves visible before the Q R S complexes in any of the leads. The Q R S complexes appear uniform in shape and duration across all leads. The rhythm appears consistent and fast in all leads. At the bottom, several arrows and markers points to specific areas along the rhythm strip, corresponding to individual Q R S complexes, which highlights the uniformity and timing of each beat.

FIG. 31.32 Ventricular tachycardia with obvious arteriovenous dissociation and independent P-waves are highlighted with *arrows* in lead II.

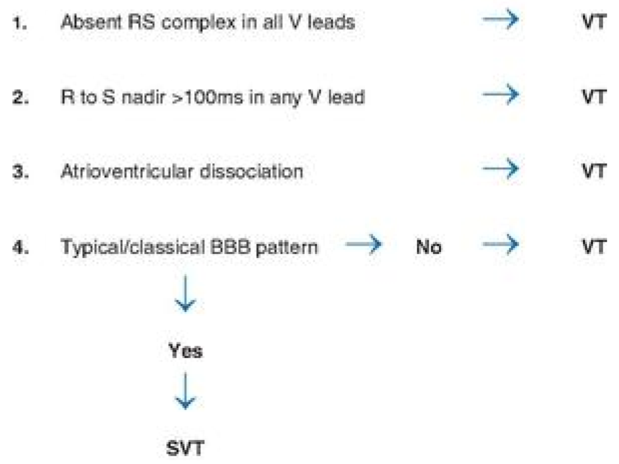


The electrocardiogram strip presents four parts on a grid background and two circular insets. Part A appears at the top and consists of a series of waveforms that represent heart electrical activity with consistent peaks and troughs. Part B is below Part A and displays similar waveforms of heart activity. Part C follows Part B and contains more waveforms with a steady rhythm. Part D is at the bottom and shows a series of heart activity waveforms. The first circular inset is above Part A and highlights a specific waveform segment. The second circular inset is above Part B and also emphasises a waveform segment. Each part includes multiple cycles of heartbeats.

FIG. 31.33 Ventricular tachycardia. Independent atrial activity can be difficult to see. Dissociated P-waves can just be seen in leads I and V_4.

ECG

Older criteria (e.g. QRS >140 ms and extreme electrical axis changes) are unhelpful in rhythm diagnosis. [59] ECG criteria initially proposed by Wellens and revised by Brugada et al. permit accurate diagnosis in four sequential steps (Fig. 31.34). [60–62]



1. Absent RS complex in all V leads → VT
2. R to S nadir >100ms in any V lead → VT
3. Atrioventricular dissociation → VT
4. Typical/classical BBB pattern → No → VT
Yes
SVT

The illustration for diagnosing heart rhythms lists four decision points with arrows pointing to outcomes. The first point states Absent R S complex in all V leads and an arrow points to V T. The second point states R to S nadir greater than 100 milliseconds in any V lead and an arrow points to V T. The third point states Atrioventricular dissociation and an arrow points to V T. The fourth point states Typical classical bundle branch block pattern. An arrow from this point leads to two options. The first option is No, with an arrow pointing to V T. The second option is Yes, with an arrow pointing to S V T.

FIG. 31.34 Algorithm proposed by Brugada et al. [60] to diagnose ventricular tachycardia in the setting of a broad QRS-complex tachycardia.

The sensitivity of these four consecutive steps was 0.987, with a specificity of 0.965.

- *Step 1:* Is an RS complex present in any precordial lead? (QR, QRS, QS, monophasic R and rSR are not considered RS complexes.) If not (Fig. 31.35), the diagnosis is VT.

- *Step 2:* If an RS is present, then measure the duration of the R-to-S nadir (lowest part of the S-wave). If this duration is >100 ms in any V lead (Fig. 31.36), the rhythm is VT.
- *Step 3:* If RS <100 ms, then AV dissociation is searched for (more QRS complexes than P-waves; see Figs 31.32 and 31.33). Indirect evidence of AV dissociation such as capture or fusion beats may be present. Capture beats occur when atrial sinus impulses reach the AV node when it is no longer refractory from retrograde conduction of ventricular discharges: the AV node and ventricle are then 'captured' by the sinus impulse. The resultant QRS will occur earlier than the next expected VT complex and the QRS morphology will be that of the 'normal' underlying complexes for that patient. Similarly, a sinus impulse can penetrate the AV and 'fuse' with an already depolarising ventricle from the ectopic focus initiating the VT. The resulting QRS morphology of a fusion beat will be variable and depend on the relative contribution of the supraventricular and ventricular impulses to ventricular activation. Even a single capture or fusion beat confirms AV dissociation and VT (Fig. 31.37).
- *Step 4:* If AV dissociation is not present, then decide whether the wide QRS has a right or left BBB (LBBB) pattern. If the BBB is typical in both V_1 and V_6 leads, the rhythm is supraventricular in origin (see the section on BBB). If there are any atypical features, the rhythm is considered to be VT.

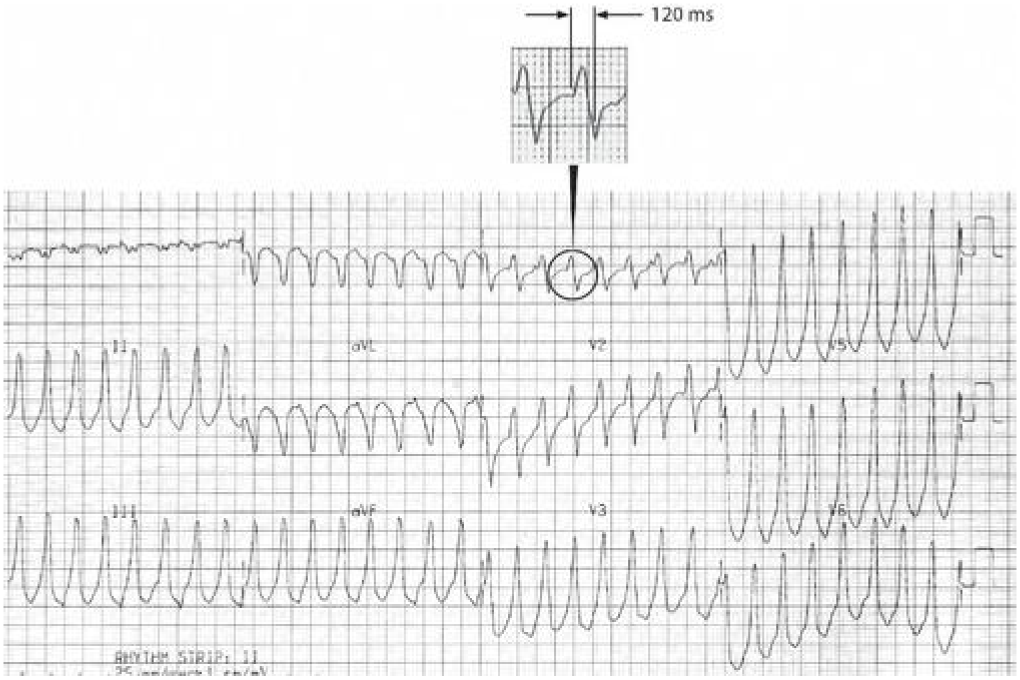
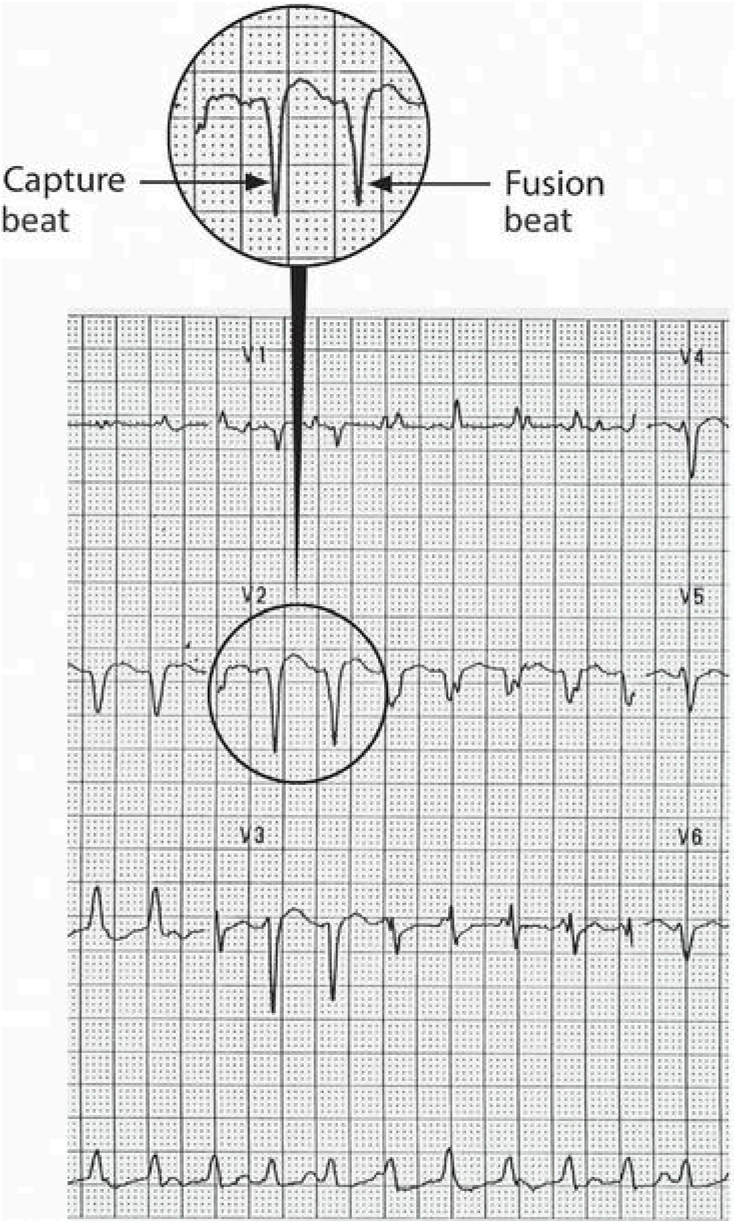
The electrocardiogram strip presents six parts labelled A and B, with three series of waveforms for each. Under Part A, the first waveform consists of a series of waveforms that represent heart electrical activity with consistent peaks and troughs. The second waveform displays similar waveforms of heart activity. The third part contains more waveforms with a steady rhythm. Under B, the first part shows a series of heart activity waveforms. The second part presents additional waveforms. The third part displays more heart activity waveforms. Each part includes multiple cycles of heartbeats.

FIG. 31.35 (A and B) Ventricular tachycardia. Broad QRS-complex tachycardia with absence of RS complex in all precordial leads.



The twelve-lead electrocardiogram displays multiple leads, including a V L, a V F, V 1, V 2, V 3, V 5, and V 6, with a rhythm strip at the bottom labelled lead two. The tracing illustrates a regular, rapid rhythm composed of broad, monomorphic Q R S complexes consistent across the leads. The Q R S complexes appear wide and consistent in morphology. The lead V 2 contains a circular marker around one of the Q R S complexes, which is connected by a line to an enlarged inset positioned above the electrocardiogram. This magnified view focuses on a single Q R S complex, which shows detailed notches and slopes within the waveform, along with a labelled measurement of 120 milliseconds. This highlights the extended Q R S duration. The morphology and duration of the wide complexes are similar in all leads. The overall pattern in each lead is consistent with a sustained episode of wide complex tachycardia.

FIG. 31.36 Ventricular tachycardia. Time duration of R to the nadir of the negative S-wave is 120 ms. Note also independent P-waves in lead V_1.



The twelve-lead electrocardiogram displays precordial leads V 1 to V 6. The lead V 2 is emphasized with a circular marker around two distinct Q R S complexes. An enlarged inset above the tracing presents a close-up view of these two waveforms. The first marked complex in the inset is labelled as a capture beat, which displays a narrow Q R S morphology indicative of partial normal conduction. The second complex is labelled as a fusion beat, with an intermediate morphology between normal and wide complex, which reflects a combination of supraventricular and ventricular activation. The remaining Q R S complexes throughout the leads are wide and uniform, consistent with a wide complex tachycardia. Leads V 1 through V 6 all show this wide rhythm pattern, with the capture and fusion beats standing out clearly in lead V 2. These beats interrupt the otherwise regular sequence of wide Q R S complexes.

FIG. 31.37 Ventricular tachycardia with a highlighted premature capture beat followed by a fusion beat showing transitional QRS morphology between the underlying normal QRS and VT complex. Note also independent P-waves.

Termination of a wide-complex tachycardia by IV adenosine strongly suggests the arrhythmia as SVT. However, adenosine in this setting has the risk of destabilising VT when blood pressure is barely compensated by causing vasodilatation or acceleration of accessory pathway conduction, and is not recommended by the International Liaison Committee on Resuscitation (ILCOR) as a diagnostic strategy in wide-complex tachycardia. [24] Demonstration of AV dissociation by intracardiac ECG from a central venous catheter or a transvenous pacing lead signifies VT.

Clinical

The major cause of VT is significant coronary artery disease. Other causes include cardiomyopathy, myocarditis and valvular heart disease. Symptoms will depend on the ventricular rate, duration of tachycardia and underlying cardiac function. There are not necessarily any haemodynamic differences between VT and SVT with aberrant conduction but haemodynamic instability mandates management as for VT.

Treatment [24]

DC shock is indicated if a patient is haemodynamically unstable. Antiarrhythmic drug trial is indicated in haemodynamically stable VT.

- Amiodarone may terminate VT; there is less negative inotropic action but a delayed effect.
- Sotalol and procainamide are more effective than lidocaine but are associated with significant myocardial depression.
- Although traditionally indicated, there are now doubts about the efficacy of lidocaine.

If drugs are ineffective, synchronised DC shock is indicated. Rapid right ventricular pacing may also be effective.

Long-term prevention of VT and sudden death is difficult. Sotalol guided by Holter ECG or electrophysiological testing, and empirical (i.e. non-guided) amiodarone are superior to other drugs in preventing arrhythmia recurrences. Empirical beta-adrenergic blockers also have a role. Implantable defibrillators can recognise and automatically terminate VT by rapid ventricular pacing or, if this fails, by internal DC cardioversion, which may be life saving. Secondary prevention of VT/VF with implantable cardioverter defibrillator (ICD) is indicated if LVEF <35%. Pre-emptive ICD has no added benefit to amiodarone treatment.

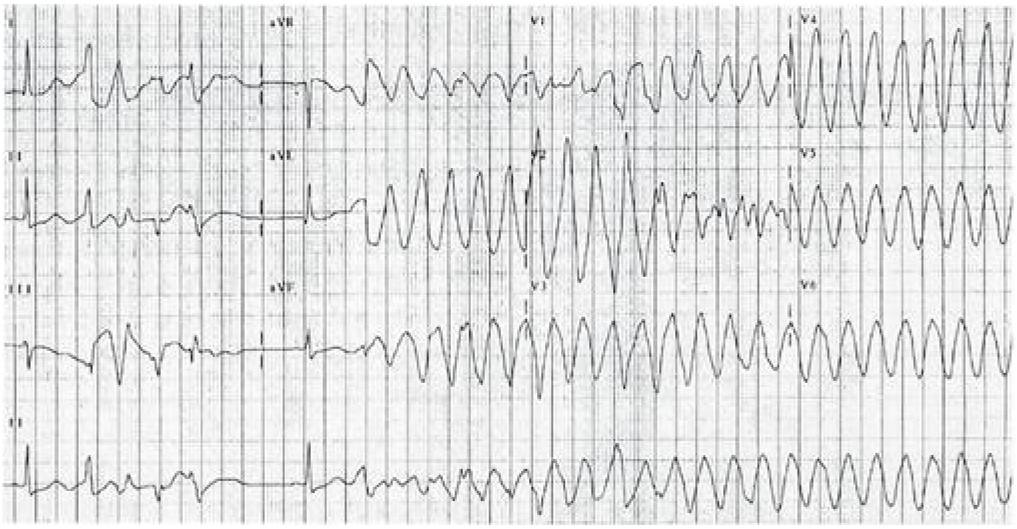
Catheter ablation is being increasingly used in the acute setting for VT storm. Patients with ICD and recurrent VT not controlled with amiodarone or another Class I or III agent had improved outcomes with ablation compared with escalation of antiarrhythmic drugs (VANISH). [63]

Management Issues with VT storm or recurrent VT

- Within 48 hours of acute coronary artery syndrome, emergency re-vascularisation indicated
- Thereafter VT ablation especially if monomorphic
- Success of ablation in ACD greater than non-ischaemic
- Re-entrant circuit tends to involve endocardium surface thereby increasing procedure success

Polymorphic Ventricular Tachycardia and Torsade De Pointes

This arrhythmia has QRS complexes at 200 beats/min or greater, which change in amplitude and axis so that they appear to twist around the baseline (Fig. 31.38). Torsade de pointes usually has prolonged QT during sinus rhythm, and U-waves are often present (see section on long-QT syndrome). However, polymorphic VT may be associated with a normal QT interval in settings such as myocardial ischaemia, infarction or post-cardiac surgery.



The twelve-lead electrocardiogram contains leads one, two, three, a V R, a V L, a V F, and precordial leads V 1 to V 6. All leads demonstrate a continuous series of broad Q R S complexes with consistent shape and amplitude. The rhythm is regular and rapid, indicative of a wide complex tachycardia. The limb lead includes a V R, a V L, and a V F, which display uniform wide complexes without visible P waves. In the precordial leads, particularly V 1 through V 6, the wide Q R S complexes appear monomorphic, which maintain similar waveform contours throughout the sequence. No normal narrow Q R S complexes are present. The rhythm shows no variation in rate or morphology, which suggests a sustained ventricular origin. The tracing does not exhibit any apparent capture or fusion beats. The Q R S duration remains prolonged throughout the recording, and the consistent waveform pattern supports a diagnosis of ongoing wide complex tachycardia across all leads.

FIG. 31.38 Torsade de pointes preceded by multifocal ventricular ectopic beats.

Treatment

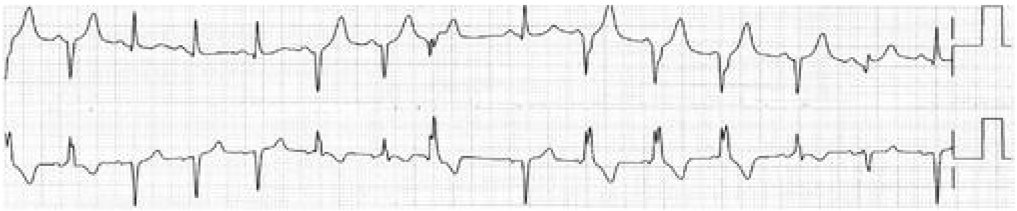
Polymorphic VT associated with a normal QT interval during sinus rhythm (e.g. following AMI) should be treated in the same way as monomorphic VT. (See section on treatment of long-QT and polymorphic VT.)

Accelerated Idioventricular Rhythm (AIVR)

This is often inappropriately called slow VT. Increased automaticity is probably the mechanism responsible for this relatively benign arrhythmia.

ECG

There is a wide QRS with a rate of 60–110 beats/min (Fig. 31.39). Sinus rate is often only slightly slower than the arrhythmia, so the dominant rhythm may be intermittent AIVR and sinus rhythm. Fusion beats are therefore common.



The electrocardiogram strip presents two parts on a grid background. Part A appears at the top and consists of a series of waveforms that represent heart electrical activity with consistent peaks and troughs. Part B is at the bottom and also displays a series of waveforms with similar patterns of heart activity. Each part contains multiple cycles of heartbeats. The grid lines help to measure the intervals between the waveforms. The strip provides a detailed view of the heart rhythm over a short period.

FIG. 31.39 Sinus rhythm with short runs of accelerated idioventricular rhythm. Note frequent fusion beats as sinus rate is similar to the accelerated idioventricular rate.

Clinical

The rhythm is commonly encountered in inferior myocardial infarction. AIVR may be misdiagnosed as VT. Occasionally, AIVR causes haemodynamic deterioration, usually due to loss of atrial systole. Increasing the atrial rate with either atropine or atrial pacing may then be necessary.

Ventricular Fibrillation

VF always causes haemodynamic collapse, loss of consciousness and death if not immediately treated. Of patients resuscitated from VF, 20%–30% have sustained an AMI, and 75% have coronary artery disease. VF (and VT) unassociated with AMI is likely to be recurrent; 50% die within 3 years.

ECG

The ECG shows irregular waves of varying morphology and amplitude (Fig. 31.40).

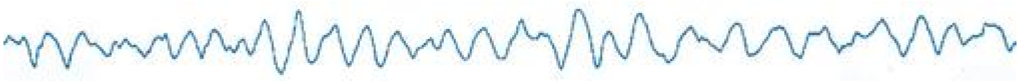


FIG. 31.40 Ventricular fibrillation with waves of varying morphology and amplitude.

Clinical

VF is usually associated with ischaemic heart disease, although other causes include cardiomyopathy, antiarrhythmic drugs, severe hypoxia and non-synchronised DC cardioversion.

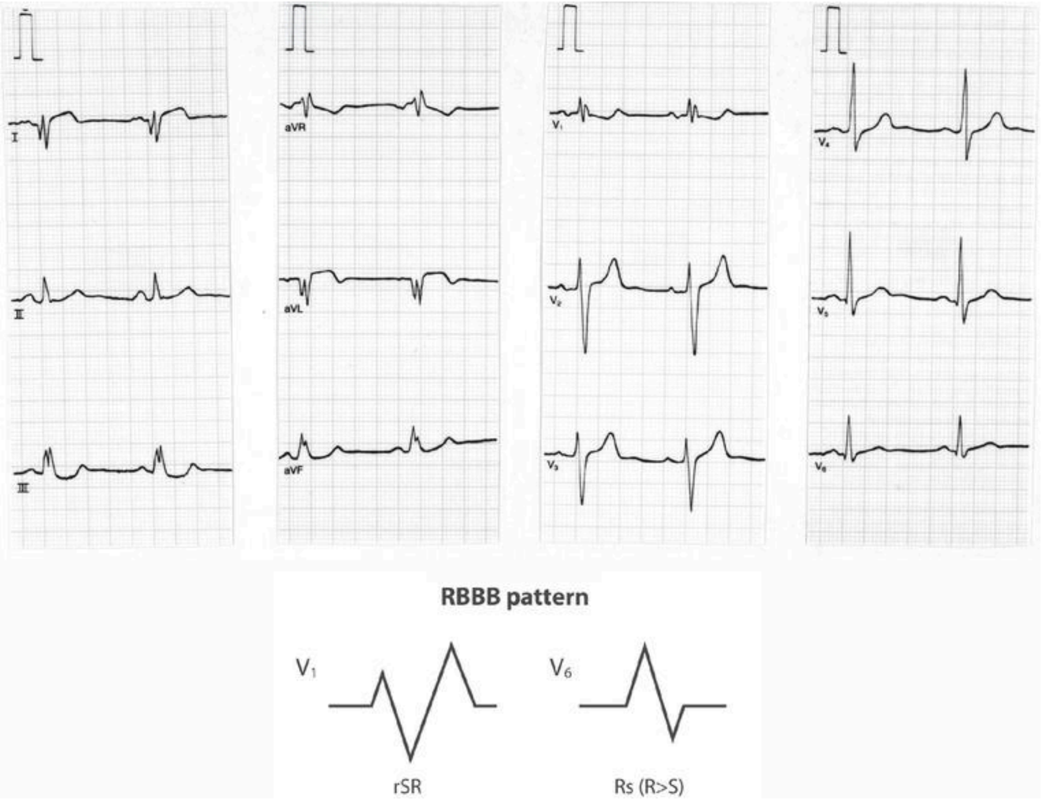
Treatment

Give an immediate asynchronised biphasic DC shock at 200 J. Time should not be wasted with basic life support if immediate defibrillation can be delivered.

If DC shock sequence fails, basic and advanced life support aiming to maximise coronary blood flow with chest compressions and vasopressors is crucial to cardiac success. Until recently, any role of antiarrhythmic drugs in DC shock-resistant VF has been traditional rather than proven. Recommendations have varied from lidocaine and bretylium to amiodarone. The ILCOR currently recommends consideration of a range of antiarrhythmic drugs, including amiodarone, lidocaine, magnesium and procainamide. Recent studies indicate amiodarone as the drug of choice for DC shock-resistant VF. Amiodarone (300 mg) was superior to lidocaine and, in another study, 5 mg/kg followed by 2.5 mg/kg if required was superior to lidocaine. There is an incidence of bradycardia and hypotension but no difference in adverse effect profile between lidocaine and this sizeable amiodarone dose.[64, 65] After return of circulation, appropriate antiarrhythmic therapy is less clear. Precipitating factors should be sought and treated (for long-term management issues, see the section on SCD).

Right Bundle Branch Block (Fig. 31.41)

In right BBB (RBBB) the normal rapid coordinated depolarisation of the right ventricle is lost due to conduction block in the right branch of the bundle of His. There is normal rapid depolarisation of the septum and the initial deflection of the QRS is not altered. The activation of the free wall of the left ventricle is also normal. However, the final activation of the free wall of the right ventricle is slow and anomalous, leading to a broad QRS.



The electrocardiogram strip presents four parts on a grid background with two additional diagrams. Part A appears at the top and consists of a series of waveforms that represent heart electrical activity with consistent peaks and troughs. Part B is below Part A and displays similar waveforms of heart activity. Part C follows Part B and contains more waveforms with a steady rhythm. Part D is below Part C and shows a series of heart activity waveforms. Part E is at the bottom and presents additional waveforms. Below the strip two diagrams labelled R B B B pattern illustrate specific waveform shapes. The first diagram labelled V 1 shows a waveform with a distinct peak. The second diagram labelled V 6 shows a waveform with a different peak pattern. Each part includes multiple cycles of heartbeats. The grid lines assist in measuring the intervals between the waveforms.

FIG. 31.41 Right bundle branch block (RBBB) with characteristic M-shaped rSR complex in lead V_1 and Rs complex in V_6.

ECG

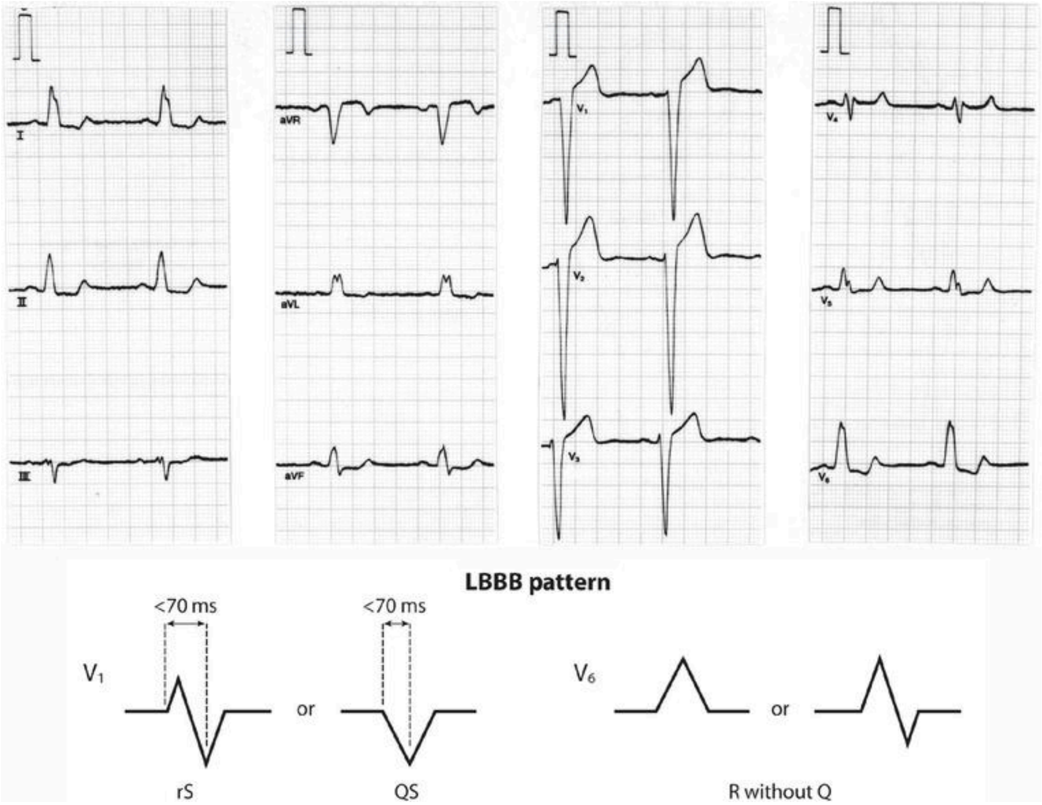
The ECG shows wide QRS (>120 ms) and the QRS morphology in the right ventricular leads V_1 and V_2 is often M shaped. This results in two R-waves, with the smaller of the R-waves being designated ‘r’ and the larger ‘R.’ The classical pattern is the M-shaped rSR in V_1 or V_2 and a broad S-wave in LV leads, especially I and V_6. In V_1 the R-wave is greater in amplitude than the R-wave. In V_6 the R-wave is greater than any S-wave present. Partial RBBB is identical, except the QRS duration is 110–120 ms.

Clinical

RBBB may be a normal variant but may occur with massive pulmonary embolism, right ventricular hypertrophy, ischaemic heart diseases and congenital heart disease (note that myocardial infarction can be diagnosed in the presence of RBBB).

Left Bundle Branch Block (Fig. 31.42)

In LBBB, there is delayed and anomalous activation of the interventricular septum from right to left (i.e. in the opposite direction to normal) and the free wall of the left ventricle.



The electrocardiogram strip presents five parts on a grid background with two additional diagrams. Part A appears at the top and consists of a series of waveforms that represent heart electrical activity with consistent peaks and troughs. Part B is below Part A and displays similar waveforms of heart activity. Part C follows Part B and contains more waveforms with a steady rhythm. Part D is below Part C and shows a series of heart activity waveforms. Part E is at the bottom and presents additional waveforms. Below the strip, two diagrams labelled left bundle branch block pattern illustrate specific waveform shapes. The first diagram labelled V 1 shows a waveform with a duration less than 70 milliseconds and labels of r S and Q S. The second diagram labelled V 6 shows a waveform with a duration less than 70 milliseconds and labels of R and R without Q. Each part includes multiple cycles of heartbeats. The grid lines assist in measuring the intervals between the waveforms.

FIG. 31.42 Left bundle branch block (LBBB).

ECG

There is a wide QRS (>120 ms) and in V_1 the characteristic morphology shows an rS or QS. In V_6 there are primary and secondary R-waves (RR′), often resulting in M-shaped or plateau morphology. Q-waves are never seen in LV leads (V_4–V_6) (note that myocardial infarction cannot usually be diagnosed in the presence of LBBB). Partial LBBB is similar, except that the QRS duration is 110–120 ms.

Clinical

LBBB is often associated with heart disease such as coronary artery disease, cardiomyopathy or LV hypertrophy. LBBB makes diagnosis of myocardial infarction difficult and the development of a new LBBB fulfils ECG criteria of acute infarction.

Hemiblocks

The left branch of the bundle of His divides into the left anterosuperior division supplying the anterior superior lateral wall of the left ventricle and the posteroinferior division supplying the posterior inferior diaphragmatic surface of the left ventricle. Although block can occur in either division, it is more common in the anterosuperior division, as it is more vulnerable to disease processes due to its longer course and thinner dimension. The anterosuperior division runs close to the aortic valve and tends to be involved in degenerative processes affecting this valve. The posteroinferior division is shorter and thicker and, unlike the anterosuperior division, has a double blood supply.

Left Anterior Hemiblock

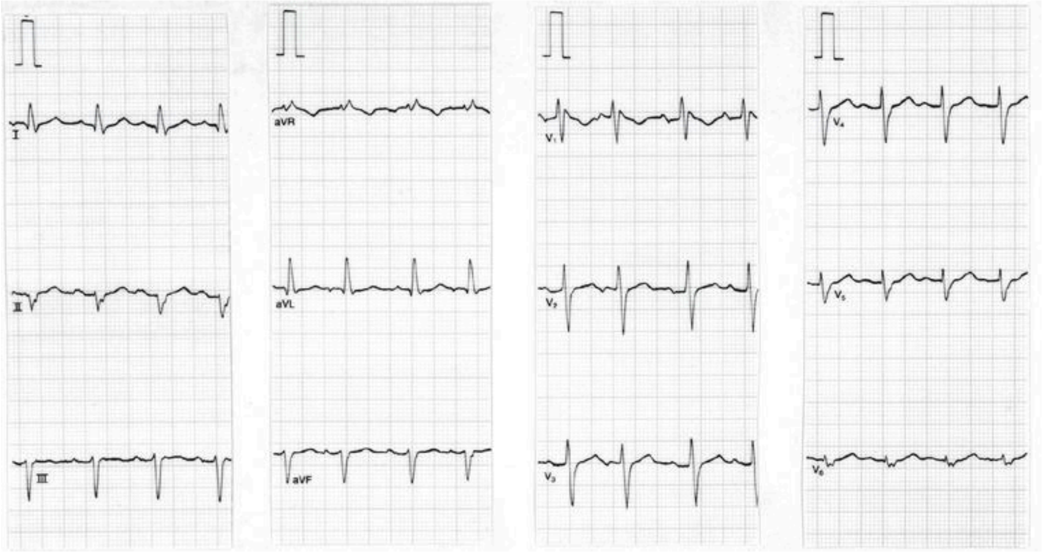
There is left-axis deviation (usually lead I predominantly positive, leads II and III predominantly negative) with initial R-wave in inferior leads (II, III, aVF).

Left Posterior Hemiblock

There is usually right-axis deviation (lead I predominantly negative and lead III predominantly positive). Other causes of right-axis deviation (e.g. right ventricular hypertrophy) need to be excluded.

Clinical

RBBB with either left anterior hemiblock (Fig. 31.43) or left posterior hemiblock indicates an extensive conduction defect and a poor prognosis (high risk of complete heart block), especially in AMI.



The electrocardiogram consists of four separate traces arranged in a two-by-two grid. Each trace presents the electrical activity of the heart. The top left traces display a series of peaks and dips representing heartbeats. The top right traces follow a similar pattern with slight variations in the wave shapes. The bottom left traces exhibit a consistent rhythm with noticeable spikes at regular intervals. The bottom right traces mirror the others but include minor differences in the wave heights and intervals between beats. All traces use a standard grid layout typical for electrocardiogram recordings.

FIG. 31.43 Right bundle branch block with left anterior hemiblock. There is left-axis deviation (mean frontal axis of −75°) and small R-waves in II, III and aVF.

Hyperkalaemia

A high serum K $^+$ can produce ECG changes (Fig. 31.44). Early changes consist of tall peaked T-waves with reduced P-wave amplitude. Progressive widening of the QRS may be confused with BBB. Cardiac arrest may eventually occur.

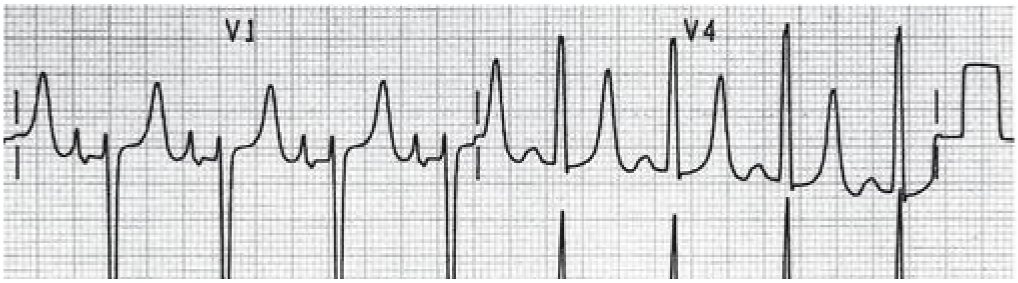


FIG. 31.44 Sinus rhythm with peaked ‘tent-shaped’ T-waves in a patient with a serum potassium of 7.6 mmol/L.

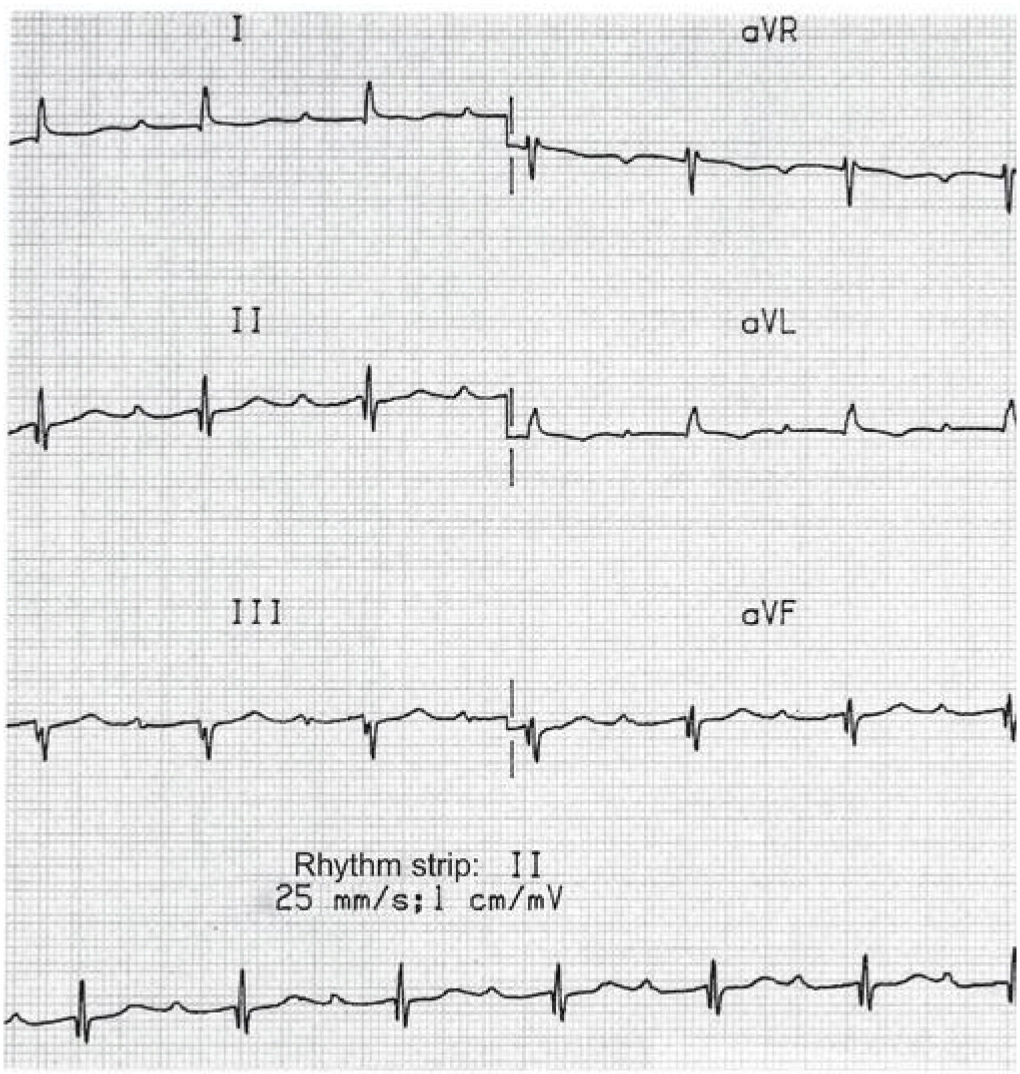
Atrioventricular Block

AV block is a delay or failure of impulse conduction from the atria to the ventricles. AV block is classified according to whether conduction of atrial impulses is delayed (first degree), blocked intermittently (second degree) or blocked completely (third degree).

First-Degree AV Block

ECG

PR interval (measured from the onset of the P-wave to the onset of the QRS) exceeds 200 ms (Fig. 31.45). Each P-wave is followed by a QRS. PR intervals may be prolonged to such a degree that the P-wave is buried in the previous T-wave or even QRS.



The electrocardiogram consists of three traces arranged vertically. The first traces labelled one and a V R present the electrical activity of the heart on graph paper with small squares. The second tracing labelled two and a V L follows with a similar pattern but includes variations in wave shapes. The third tracing labelled three and a V F exhibits a consistent rhythm with noticeable spikes at regular intervals. Below the tracings, a rhythm strip labelled one displays a continuous heart rhythm pattern. A note at the bottom states 25 millimetres per second and one centimetre per millivolt, indicating the scale of the recording.

FIG. 31.45 Sinus rhythm with first-degree AV block. The PR interval is 360 ms. Note inferior-wall myocardial infarction with Q-waves in II, III and aVF.

Clinical

First-degree AV block is commonly associated with increased vagal tone, and occasionally with drugs (especially digoxin), ischaemic heart disease (particularly inferior myocardial infarction) and rheumatic fever. It usually causes no symptoms and requires no treatment. If associated with digoxin, the drug should be ceased or the dose decreased.

Second-Degree AV Block

Second-degree AV block is characterised by intermittent failure of AV conduction and is classified into Mobitz types I and II. Second-degree AV block can occur in SVTs; however, the conduction block is a physiological ‘protective’ mechanism in the setting of rapid atrial impulses.

Mobitz Type I (Wenckebach)

Delay in AV conduction increases with each atrial impulse until an atrial impulse fails to conduct. This is usually a repetitive pattern, which may or may not begin with first-degree AV block. The level of AV block in type 1 is usually in the AV node itself and can be physiological (increased vagal tone) as well as pathological.

ECG

There is progressive lengthening of the PR interval over successive cardiac cycles, culminating in a non-conducted P-wave, resulting in a missed beat (Fig. 31.46). Type 1 is common in fit healthy people in the presence of high levels of resting vagal tone (Fig. 31.47).

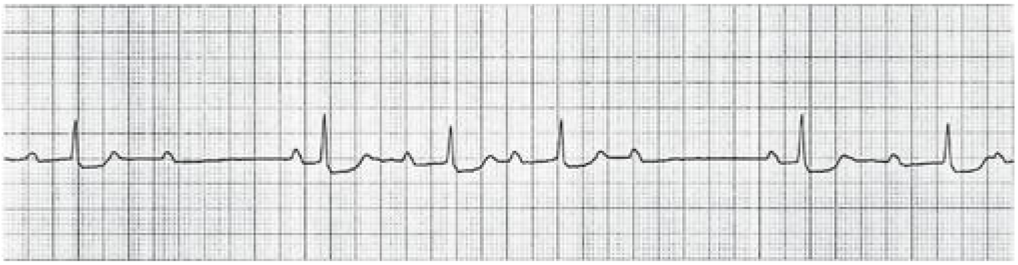


FIG. 31.46 Mobitz type I (Wenckebach) second-degree arteriovenous block. Progressive lengthening of PR interval results in the failure of the second and sixth P-wave to be conducted.

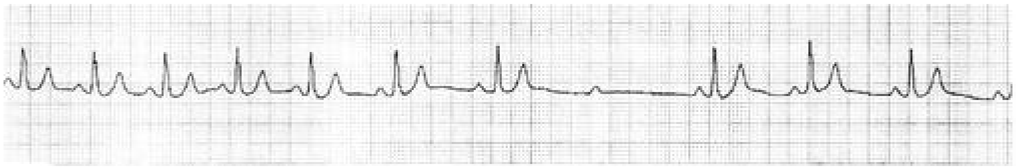

FIG. 31.47 Intermittent type I second-degree arteriovenous block in a healthy male with obvious background sinus arrhythmia. Constant PR interval of 0.14 seconds suddenly increases to 0.22 seconds and next P-wave is not conducted.

Clinical

The condition is generally benign and does not carry the adverse likelihood of progression to complete AV block, although it may occur with inferior infarction. Treatment is rarely necessary.

Mobitz Type II

There is intermittent failure of conduction of atrial impulses to the ventricles without preceding increases in the PR interval. The ratio of conducted to non-conducted atrial impulses varies; for example, every second or fourth atrial impulse may be conducted (i.e. 2:1 or 4:1 second-degree AV block). The lesion causing type II is usually situated in the bundle of His and is always pathological.

ECG

PR interval remains constant prior to the blocked P-wave. There is always a constant P-QRS-wave ratio: the P-waves are two (Fig. 31.48), three (rare) or four times more frequent than QRS waves.

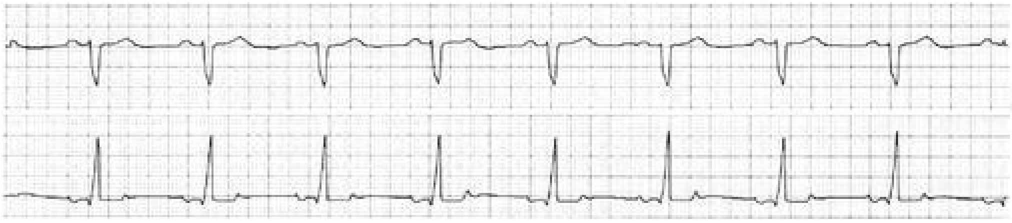

FIG. 31.48 Mobitz type II second-degree arteriovenous (AV) block. Persistent 2:1 AV block with the atrial rate at 108 beats/min and the ventricular rate at 54 beats/min.

Clinical

It is likely to be associated with structural heart disease. Slower symptomatic ventricular rates may require pacing. The AV block may be intermittent or persistent. The adverse prognosis relates to the frequency of progression to complete AV block.

Third-Degree (Complete) AV Block

This rhythm occurs when no atrial impulses are conducted to the ventricles; atrial and ventricular contractions are dissociated. The SA node usually continues to depolarise the atria, whereas ventricular activation depends on a standby escape pacemaker located below the block. The escape pacemaker may be close to the His bundle (narrow QRS, stable pacemaker usually 40–60 beats/min) (Fig. 31.49), or more distal in ventricular tissue (wide QRS, relatively unstable pacemaker with a rate of 20–40 beats/min) (Fig. 31.50). If no ectopic escape pacemaker emerges, ventricular asystole will occur, resulting in a Stokes–Adams attack, or death if the episode is prolonged. Torsade de pointes may also occur associated with bradycardia.

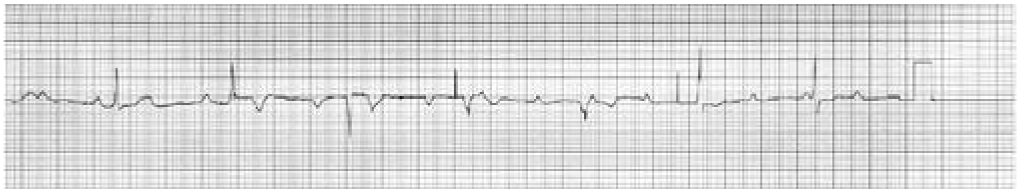

FIG. 31.49 Leads I, aVR, V_1 and V_4 showing third-degree arteriovenous block. Complete dissociation of atrial activity at a rate of 107 beats/min and the ventricular rate at 46 beats/min. The escape rhythm is junctional (high up in the bundle of His) with a narrow QRS morphology.

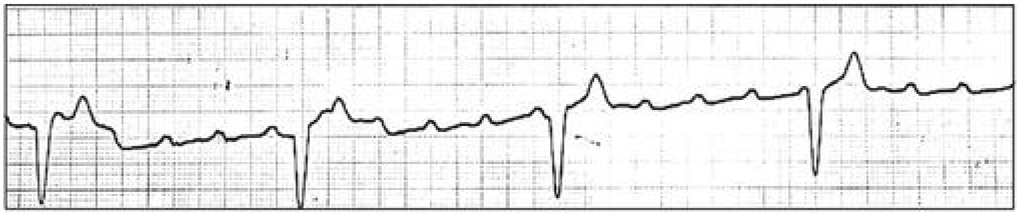

FIG. 31.50 Third-degree arteriovenous block with an atrial rhythm at 135 beats/min and a broad distal ventricular escape rhythm which is unstable at a rate of 30 beats/min.

ECG

The ECG shows normal regular P-waves completely dissociated from QRS complexes. The QRS rate is always significantly slower than the P-wave rate and may be very slow at times.

Clinical

Idiopathic fibrosis of the conduction system is the most common cause. Other causes include myocardial infarction, valvular heart disease, cardiac surgery and a congenital form of complete heart block. Cardiac pacing is usually required to increase heart rate and cardiac output. Congenital forms often have a relatively fast escape ventricular rate, and patients may remain asymptomatic for many years.

Sinus Node Dysfunction [66]

Sinus node dysfunction (SND) results in sick sinus syndrome and or atrial arrhythmias. The incidence increases from 1 per 1000 at 45 years to 1 per 600 at 65 years. Time from development of bradycardia to SA block and sinus arrest is 13 years (range 7–29 years). SND is associated with a 4.2-fold increase in AF. SND presents as AF in 40%–70% of cases. SND also presents with syncope, heart failure, other atrial tachyarrhythmia and thromboembolic events.

SND is secondary to decreased impulse generation or defective conduction out of the node resulting in bradyarrhythmia and atrial tachyarrhythmia.

Causes of SND

- Intrinsic
  - Interstitial fibrosis
    - Ischaemia
    - Infiltration: Amyloid
    - Inflammation: Rheumatic fever
    - Genetic mutation channelopathy: Decreased I_{Na} propagation causing exit block
- Extrinsic
  - Autonomic tone
    - Drugs
    - Hypothyroid
    - Hypothermia

Sick sinus syndrome occurs in the setting of chronic SND.Results in

- Severe sinus bradycardia
- Sinus pauses
- Sinus arrest
- SA nodal exit block

Chronotropic incompetence. Inappropriate response to physiological demands such as exercise and stress.

Tachybradycardia. AF (most common), Afl and sinus tachycardia.

Most AF originates from left atrium and in SND the propensity of AF is explained by loss of overdrive modulation of pulmonary vein sleeves where increases in If current results in increased spontaneous activity. Impaired non-uniform conduction out of the SN also creates substrate for re-entry.

Atrial tachycardia and AF result in significant SND within 2 weeks due to downregulation of I_f and SND increases propensity of atrial tachyarrhythmia further.

SND recovers following AF reversion, either ablation or cardioversion.

Drug therapy is difficult in SND and tachybrady arrhythmia. If adequate chronotropic response to exercise can be demonstrated, then beta-blocker with intrinsic sympathomimetic activity can be trialled. Otherwise, all agents have negative chronotropic action and concurrent pacemaker is indicated.

Permanent pacemaker (PPM) with AAI or DDD mode reduces AF, stroke and pacemaker syndrome compared with VVI.

AF ablation improves SND, decreases bradycardia and the need for pacemaker when compared to PPM and antiarrhythmic drugs (Fig. 31.51).

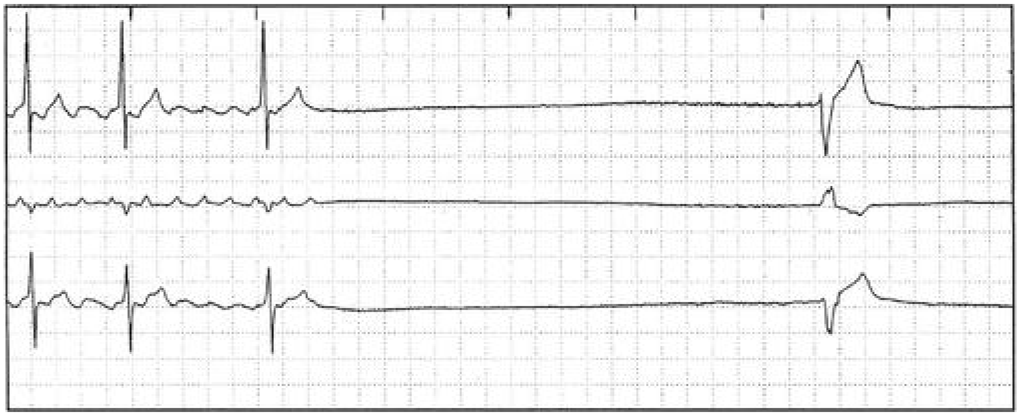

FIG. 31.51 Characteristic findings in sick sinus syndrome. Episodic atrial tachycardias (atrial flutter with variable block in this instance) with periods of sinus arrest and very slow ventricular escape rhythm upon spontaneous termination in this case following carotid sinus massage.

Critically Ill Patients and Arrhythmia [67]

In the general population of critically ill patients, excluding acute coronary syndromes and cardiac surgical patients, arrhythmia is common. The documented incidence is as high as 78%; however, the incidence of arrhythmia that requires treatment is much lower, at 15%–30%. SVT is by far the most common arrhythmia that requires treatment. AF, Afl and unifocal atrial tachycardias are the most frequent, in descending order. These SVTs are rarely the cause of admission but develop early in the admission, the majority by day 2. In critically ill patients, SVTs often result in:

- adverse myocardial oxygen supply–demand balance
- compromised blood pressure, cardiac output and systemic oxygen delivery
- impaired end-organ function such as oliguria and worsening gas exchange.

The development of SVT in a critically ill patient is associated with a significant increase in mortality, especially in patients with sepsis and respiratory failure. Incidence of SVT is increased with:

- elderly patients
- evidence or past history of heart disease
- haemodynamic features of diastolic failure with elevated pulmonary artery occlusion pressure
- catecholamine infusion
- severe sepsis.

The actual dose of the catecholamine infusion does not appear to be important and, although electrolyte disturbances are common in critically ill patients, low plasma potassium and magnesium levels do not appear to be important predictors of SVT development. The incidence of SVT, particularly AF, is so high in elderly patients with heart disease on a catecholamine infusion that consideration of prophylactic strategies is worthwhile.

Risk of in-hospital stroke is increased in critically ill patients with new-onset AF, odds ratio of 2.70 and greater focus on the need for embolic prophylaxis is needed. [68]

Treatment of Supraventricular Tachycardia in Critically Ill Patients

Continuing arrhythmogenic and chronotropic factors make rate control difficult.

- Digoxin often results in poor rate control due to persisting endogenous and exogenous sympathomimetic tone. The inotropic and vasopressor effects of acute digitalisation are beneficial. Digoxin (10 µg/kg) has been shown to provide superior circulatory support to dopamine at 8 µg/kg per min in septic patients. [69]
- Irrespective of plasma levels, magnesium has been shown to be effective at rate control; however, hypotension due to vasodilatation can be seen.
- Amiodarone is particularly effective and has allowed reliable acute rate control over a period of days in critically ill patients with circulatory shock requiring catecholamine infusions. [70] It can cause hypotension if patients are rapidly loaded. In another study, magnesium was at least as effective as amiodarone in rate control and time to reversion to sinus rhythm. [71]
- Other agents, such as diltiazem, sotalol and procainamide, are associated with prohibitive myocardial depression and hypotension.

Urgent cardioversion is indicated in unstable patients. The likelihood of remaining in sinus rhythm in the setting of high endogenous and exogenous sympathomimetic tone is low without concomitant use of an antiarrhythmic drug. Cardioversion is best reserved for hastening the onset of sinus rhythm once a drug like amiodarone has controlled rate. Cardioversion should at least be attempted within 24–48 hours of onset in the hope that embolic and anticoagulation issues are avoided.

Myocardial infarction and arrhythmia

Arrhythmia is common following AMI. While early arrhythmia contributes significantly to mortality, treatment is largely expectant and secondary to re-establishing coronary blood flow, minimising infarct size and treating ongoing ischaemia and heart failure. Late ventricular arrhythmia is particularly challenging, as selecting patients at risk is difficult and treatment options are limited.

Management of Acute Myocardial Infarction and Arrhythmia Control

Modern management of AMI, although targeted to prevent or reduce infarct size, has also been very effective in reducing arrhythmia incidence and sequelae. Numerous studies have documented transient ventricular arrhythmias at the time of reperfusion resulting from thrombolysis and acute angioplasty. However, the most common arrhythmias seen in this setting are VEB, AIVR and non-sustained VT, rather than VF or sustained VT.

Meta-analysis of thrombolytic trials has shown no increase in early VF following thrombolytic therapy in the first 24 hours. The likelihood of developing VF at any time during a hospital episode is reduced following thrombolytic therapy but the risk of developing VT is increased. The mechanism of reperfusion arrhythmia is believed to be related to intracellular calcium overload and the resulting triggered activity in the form of DAD. Dipyridamole, which inhibits the cellular uptake of adenosine, has been shown to be effective in preventing and treating reperfusion ventricular arrhythmia.

Prior to the introduction of reperfusion therapy, beta-adrenergic receptor blockers significantly reduced the incidence of early VEB and VF. However, following routine use of reperfusion therapy, the benefit of beta-blockers relates to a reduction in post-infarction ischaemia and subsequent infarction.

The early work demonstrating survival benefit of magnesium was initially thought to be due to the prevention of arrhythmia. [72] However, the

Leicester Intravenous Magnesium Intervention Trial (LIMIT-2) found the improved survival not to be related to a reduction in arrhythmia. [73] Subsequent studies in the thrombolytic era have failed to show any benefit at all with magnesium, although debate regarding optimal time of administration persists. Magnesium may have a role in patients in whom beta-adrenergic blockers or thrombolytic therapy are contraindicated.

Electrolyte Concentrations and Arrhythmia Following Acute Myocardial Infarction

Serum potassium following AMI is negatively correlated with the incidence of VEB and VT, with the probability of VT falling until serum potassium exceeds 4.5 mmol/L. [11] There is no evidence that magnesium levels in this setting have any effect on ventricular arrhythmia. Nonetheless, ILCOR recommendations not only include the maintenance of serum potassium greater than 4.0 mmol/L, but also serum magnesium levels greater than 1.0 mmol/L.

Bradyarrhythmias Post Acute Myocardial Infarction

One-third of patients with AMI develop sinus bradycardia because of increased vagal tone. In inferior infarcts due to occlusion of the right coronary artery, bradyarrhythmia is due to ischaemia of the SA and AV nodes. Reperfusion of the right coronary artery can also lead to sinus bradycardia and heart block that is due to the accumulation of adenosine in nodal tissue. Bradycardia in this setting is resistant to atropine.

Second- or third-degree AV block occurs in approximately 20% of AMI patients. High-degree AV block occurs early when present, with 42% presenting with AV block and most, 66%, developing in the first 24 hours. Similar to all post-AMI arrhythmias, reperfusion therapy has reduced the incidence down to 12%. When present, high-degree AV block is associated with increased mortality. However, high-degree AV block is not an independent predictor, but rather a marker of extensive infarction and LV dysfunction.

Treatment is only indicated for sinus bradycardia associated with symptoms, hypotension or signs of poor cardiac output. Most often, first- and second-degree blocks also do not need treatment. Mobitz type I second-degree block may require treatment and atropine is indicated. However, in Mobitz type II, atropine usually has no effect on infranodal block and may precipitate third-degree block by increasing sinus rate and enhancing block. Atropine may improve heart rate with AV block occurring at the AV node, as demonstrated by a narrow QRS complex, by improving AV conduction or accelerating escape rhythm. Atropine is not indicated for infranodal third-degree block, which is diagnosed by the presence of a new wide QRS complex. When required, atropine is administered, 0.5–1.0 mg every 3 minutes until signs or symptoms are resolved, up to a maximum of 0.03–0.04 mg/kg. If atropine is not indicated or effective, cardiac pacing is required (Box 31.6). Transcutaneous pacing is indicated for initial management as a bridge until a transvenous temporary pacing wire can be inserted safely and with appropriate sterile technique. With the ready availability of transcutaneous pacing, IV catecholamines for bradyarrhythmias are to be avoided in the setting of AMI.

Box 31.6

Indications for pacing following myocardial infarction

Haemodynamically unstable bradycardia (<50 beats/min)

- Mobitz type II second-degree atrioventricular block
- Third-degree heart block
- Bilateral bundle branch block
- Left anterior fascicular block
- New left bundle branch block
- Bundle branch block and first-degree atrioventricular block

Atrial Fibrillation Post Acute Myocardial Infarction

New-onset AF occurs in 10%–15% of AMI. The incidence increases with age, large infarcts, LV hypertrophy and congestive cardiac failure. It is also related to atrial infarction with occlusion of the right coronary artery proximal to the sinus node branch or circumflex proximal to the left atrial circumflex branch. Later in the course of myocardial infarction, AF is related to post-infarct pericarditis.

Reperfusion therapy has reduced the incidence of AF. In the setting of AMI, AF is usually self-limiting and requires no treatment. If rapid ventricular rates are associated with further ischaemic symptoms or haemodynamic compromise, cardioversion is indicated. Beta blockers, which are indicated in the treatment of AMI anyway, are the initial treatment of choice. Digoxin is not indicated in the setting of acute ischaemia as the likelihood of triggered activity associated with intracellular calcium overload is increased. AF following AMI is associated with an increase in mortality. Systemic emboli following AMI are three times more likely with AF and 50% occur in the first 24 hours of onset of AF. For this reason, sustained AF is an indication of anticoagulation prior to the normal 48-hour period following AMI.

Ventricular Arrhythmia Post Acute Myocardial Infarction [74, 75]

VF/VT is the leading cause of mortality following AMI. Fifty percent of patients dying from AMI do so pre-hospital due to VF/VT. Pre-hospital mortality is being reduced by improved community education, wider application of basic life support and availability of an automated external defibrillator (AED). Following admission to hospital, LV failure is the most common cause of death.

The major risk period for VF is the first 4 hours following onset of symptoms, with 4%–18% of patients having VF in this period. Once admitted to hospital, 5% develop VF, mostly in this first 4-hour period. VF in this early 4-hour period is termed ‘primary VF’. VF later in the course of an AMI, usually associated with LV failure or cardiogenic shock, is called 'secondary VF.'

Reperfusion therapy has reduced VF incidence. The Gruppo Italiano per lo Studio della Streptochinasi nell'infarto miocardico (GISSI) study [74] found an incidence of primary VF of 3.6% and secondary VF of 0.6%. The overall incidence of ventricular arrhythmia in the Global Utilisation of Streptokinase and Tissue plasminogen activator to treat Occluded arteries (GUSTO-1) report was VF, 4.1%, VT, 3.5% and both, 2.7%.

Primary VF increases in-hospital mortality and complications but not long-term mortality. Complex ventricular arrhythmias, defined as multiform VEB, couplets and non-sustained VT, occur in 35%–40% of patients during hospital stay. They occur equally with Q-wave and non-Q-wave infarction. Complex ventricular arrhythmia is a risk factor for subsequent VF/VT and SCD, particularly in non-Q-wave infarction. Polymorphous VT is less common after AMI and does not appear to be related to QT prolongation or electrolyte disturbances in the reported cases.

Lidocaine reduces primary VF by 33% but mortality is increased by a similar amount such that there is no net benefit and the Third International Study of Infarct Survival (ISIS-3) reported an overall trend of increased mortality. Being more selective as to which patients receive lidocaine has not been possible, as only 50% of patients who develop VF have 'warning' ventricular arrhythmia. In the 'percutaneous coronary intervention or thrombolytic and beta-blocker' era of treatment of AMI, the use of prophylactic lidocaine, or any other antiarrhythmic drug, to prevent VF will have even less benefit. There are no conclusive data to support the use of lidocaine to prevent recurrent VF in those patients who have already suffered an episode of VF. Despite this, a short period of 6–24 hours of lidocaine has been advocated.

Patients who survive a late or secondary episode of VF/VT following myocardial infarction require full evaluation for preventive strategies, as do survivors of SCD. All survivors of a myocardial infarction are at an increased risk for SCD but accurate prediction is not feasible. Risk factors that have been shown to be associated with increased risk of a subsequent episode of VF/VT after myocardial infarction include:

- age
- Holter monitoring and demonstration of non-sustained VT, couplets and frequent VEB (i.e. >10 beats/min)
- impaired LV function (i.e. ejection fraction less than 30%–40%)
- signal-average ECG and detection of delayed afterpotentials. In patients presenting with SCD after myocardial infarction, 68%–87% have an abnormal signal-average ECG. However, the positive predictive value is poor, at 15%–25%
- demonstrated inducibility of VT post-infarction is associated with an increased risk of SCD. However, the positive predictive value is again poor, at 20%–30%.

Combinations of these risk factors have been evaluated to predict risk after infarction. The combination of delayed potentials on signal-average ECG, LV ejection fraction of less than 40% and non-sustained VT on Holter monitor has been shown to be associated with up to 50% risk of SCD. Currently, there is no agreement on which patients require primary preventive strategies for VF/VT following myocardial infarction.

Using frequent VEB to identify patients at risk following myocardial infarction has been extensively used. There have been 54 randomised trials reported involving more than 20,000 patients using 11 different class I agents.

Class I agents showed no overall benefit on all-cause mortality and class IC agents have excess mortality despite arrhythmia suppression.

Class II antiarrhythmics, beta blockers, have an established and broadening role, with evidence showing significant benefit. [76]

Class III agents lack a consistent class effect. Sotalol (Survival with oral d-sotalol: SWORD) was found to increase all-cause mortality and arrhythmia deaths. [77] Amiodarone (Canadian Amiodarone Myocardial Infarction Arrhythmia Trial: CAMIAT) reduces all-cause mortality in patients with frequent VEB post-myocardial infarction, [78] but another study (European Myocardial Infarction Amiodarone Trial: EMIAT) evaluated amiodarone in patients with ejection fraction less than 40% and found no effect on all-cause mortality but a 35% reduction in arrhythmia deaths. [79] Subsequent analysis of combined CAMIAT and EMIAT data has emphasised the importance of beta blockers. The combination of amiodarone and beta blockers in these post-infarct patients was better than either drug alone. [80]

Cardiothoracic surgery and arrhythmia

SVT After Cardiothoracic Surgery [81]

AF predominates, with Afl and unifocal atrial tachyarrhythmia also commonly occurring after CABG, with an incidence of 11%–40% and over 50% following valvular surgery. In addition to mechanisms found in non-surgical patients, pericardial inflammation or effusion, increased catecholamine production and postoperative autonomic changes are implicated. Major risk factors include:

- previous history of AF
- increasing age
- postoperative withdrawal of beta-blocker therapy.

Extent of coronary artery disease, postoperative ischaemia, duration of aortic cross-clamping or cardiopulmonary bypass and method of myocardial protection do not influence incidence. SVT post cardiothoracic surgery is not a benign event, with the major consequence being thromboembolic complications. Stroke occurs following CABG in 1%–6% of patients and postoperative atrial tachyarrhythmia increases the incidence threefold. Other adverse effects include:

- haemodynamic instability
- prolonged inotropic support
- need for intra-aortic balloon pump
- reoperation for bleeding
- longer and more expensive critical care units and hospital episodes.

Prevention of Supraventricular Tachycardia [82], [83]

Preoperative beta-blocker treatment should be continued postoperatively if tolerated from a heart rate and cardiac output perspective. Beta blockers consistently reduce SVT across many studies with differing agents.

Amiodarone prophylaxis after elective cardiac surgery reduced postoperative AF from 53% to 25%. Diltiazem has also been shown to be effective at SVT prevention and there was associated improvement in haemodynamic variables and rates of myocardial ischaemia. Verapamil is not effective. Esmolol was found to be more effective than diltiazem. Sotalol is also effective but problematic bradycardia and hypotension are greater.[84] Atorvastatin is also effective.[85]

There is no relation between SVT incidence and serum magnesium levels and there are conflicting data relating to the efficacy of prophylactic magnesium. Digoxin has no role in prevention.

Incidence of postoperative AF is still high despite preventive strategies. In a large cohort of patients, overall AF incidence was 33% (28.1% CABG only, 33.7% valve only and 47.3% combined) despite 80% preventive beta blocker or calcium channel blocker (Cardiothoracic Surgical Trials Network (h)). Average onset of AF was 2.4 days (range 0–7).

Treatment of Supraventricular Tachycardia

Treatment is aimed at controlling of ventricular rate, prevention of thromboembolism and cardioversion.

Similar to other settings, rhythm control is not superior to rate control. Amiodarone, AV blocker and electrical cardioversion compared to AV blocker only (resting rate <100) had similar hospital length of stay, rates of anticoagulation and stable sinus rhythm at discharge, complications, including thromboembolic, stable sinus rhythm at 30 and 60 days and readmission rates.[86]

Digoxin, atenolol/metoprolol, diltiazem and magnesium are appropriate choices to control rate.

In persisting AF, the timing of electrical cardioversion is debatable. Early electrical cardioversion, within 24–48 hours, avoids the need for anticoagulation but is associated with a significant recurrence rate as postoperative arrhythmogenic factors remain. In persistent or recurrent AF, sotalol and amiodarone, depending on myocardial function, are suitable antiarrhythmic drugs and should be continued for 6–12 weeks following cardioversion.

Timing of safe anticoagulation following cardiac surgery is also debatable. Many advocate delaying anticoagulation till 72 hours post surgery, which may be greater than 24–48 hours after onset of SVT. Most cardiac surgical patients receive aspirin and low-dose heparin in the early postoperative period, which is likely to reduce risk. However, it is worth noting that, in other AF settings, 325 mg of aspirin decreased thromboembolic events but 75 mg did not.

Ventricular Arrhythmia Following Cardiac Surgery

Ventricular arrhythmia requiring treatment, DC shock or drug therapy is common following cardiac surgery and occurs in 23% of patients.[87] Arrhythmias requiring DC shock occur in the first 36 hours and are associated with:

- advanced age
- failure to use an internal mammary artery conduit (which is likely to reflect preoperative assessment of high risk)
- SVT.

The incidence was not related to previous myocardial infarction, ejection fraction of less than 50%, prolonged operative time, perioperative myocardial infarction or reduced number of vessels bypassed. In patients undergoing coronary artery bypass, patients at high risk for sudden death, LV ejection fraction less than 36% and abnormalities on signal-averaged ECG had a 6.3% incidence of sustained VT and 4.3% VF.

VEBs are common early on return from surgery, with frequent or complex ectopy associated with adrenergic effects of emerging from anaesthesia and hypokalaemia. The threshold to treat these arrhythmias varies with clinicians. Potassium must be regularly checked and maintained above 4 mmol/L.

If there is accompanying emergent hypertension, in addition to the antiarrhythmic action, the vasodilating properties of magnesium provide an ideal profile at this stage. Patients with VT/VF reverting with DC shock who are haemodynamically stable should have prophylactic antiarrhythmic cover until adrenergic stimulation associated with awakening and weaning from mechanical ventilation is past. Lidocaine has been the agent of choice, but magnesium, amiodarone and sotalol are all more effective. Maintaining antiarrhythmic levels of magnesium may not be conducive to weaning from ventilation. Extrapolating from post-myocardial infarct data would support the conversion to beta blockers if there were no contraindications.

A smaller proportion of patients develop malignant VF/VT, most often in association with poor LV function and a postoperative low-cardiac-output state requiring catecholamine infusions. In this setting, ventricular arrhythmia is common, often initiated by short-coupling polymorphous VT (normal QT_c), due to ongoing ischaemia or reperfusion of ischaemic heart.

- High-dose amiodarone may work best in combination with antiarrhythmic levels of magnesium (1.8–2.0 mmol/L) or lidocaine.
- Many of these patients need an intra-aortic balloon pump to defend coronary artery perfusion pressure not only because of the likely poor LV function and low-output state but also to minimise the adverse effects of antiarrhythmic drugs and recurrent DC shocks.
- Pacing may be required to counteract bradyarrhythmia associated with escalating doses of antiarrhythmic drugs. Pacing at faster rates (90–110 beats/min, which may not be ideal from a cardiac output point of view) may be protective against recurrent episodes by promoting homogeneity of depolarisation and suppression of abnormal automaticity. The presence of epicardial or transvenous pacing wires also enables bedside-programmed stimulation and

overdrive pacing for termination of recurrent VT, which has fewer deleterious effects than recurrent DC shocks.

Arrhythmia During Pregnancy [88]

Cardiac arrhythmia is the most common cardiac complication during pregnancy.

Mechanism thought to result from increased plasma volume and stroke volume. Activation of stretch-activated ion channels (see above) results in EADs, shortened refractoriness and slowed conduction with spatial dispersion.

The majority of antiarrhythmic drugs are Category C (www.fda.gov). Risk cannot be ruled out. Amiodarone is teratogenic and associated with fetal hypothyroidism, growth retardation and prematurity and therefore is reserved for life-threatening arrhythmia. Dronedarone is also teratogenic and contraindicated. With other drugs, avoid use during organogenesis of the first trimester. Monitor fetal growth, cardiac rhythm and uterine contractility during the second and third trimesters.

Electrical cardioversion is indicated for haemodynamic instability and drug-refractory arrhythmia, and does not compromise blood flow to fetus and risk of fetal arrhythmia is small. Premature labour is theoretical risk only. There are rare cases of emergency caesarean section due to fetal arrhythmia and therefore fetal monitoring is advisable.

Catheter ablation is not indicated due to radiation exposure and potential haemodynamic instability.

Frequent atrial and VEs can be intolerable. Metoprolol (Cat C), not atenolol (Cat D, positive evidence of risk), can be used after the first trimester.

SVT is the most common sustained arrhythmia during pregnancy and 20% of patients with pre-existing SVT will have exacerbation during pregnancy. If vagal manoeuvres fail, Adenosine is safe (Cat C), with Metoprolol or Verapamil (Cat C) next in line. For SVT associated with accessory pathway (pre-excitation, stable wide-complex tachycardia) Procainamide (Cat C) is indicated and flecainide (Cat C) for prevention.

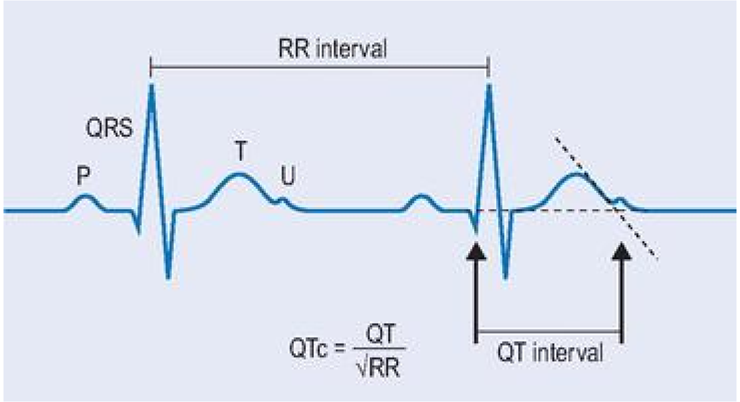
AF and Afl are less common than SVT. In new AF, pulmonary embolus and cardiomyopathy should be excluded. If unstable cardioversion is suggested, otherwise metoprolol and or digoxin (Cat C) for rate control. Sotalol (Cat B) or flecainide for failure of rate control. Anticoagulation with Enoxaparin is indicated.

VT with structural heart disease, usually in the setting of acute or chronic cardiomyopathy, should be terminated with DC shock. Lidocaine (Cat B) or Procainamide if DC shock resistant. Prevention with metoprolol or sotalol. For VT without structural heart disease, prevention with Flecainide is indicated.

For fetal SVT, flecainide, sotalol and digoxin are indicated.

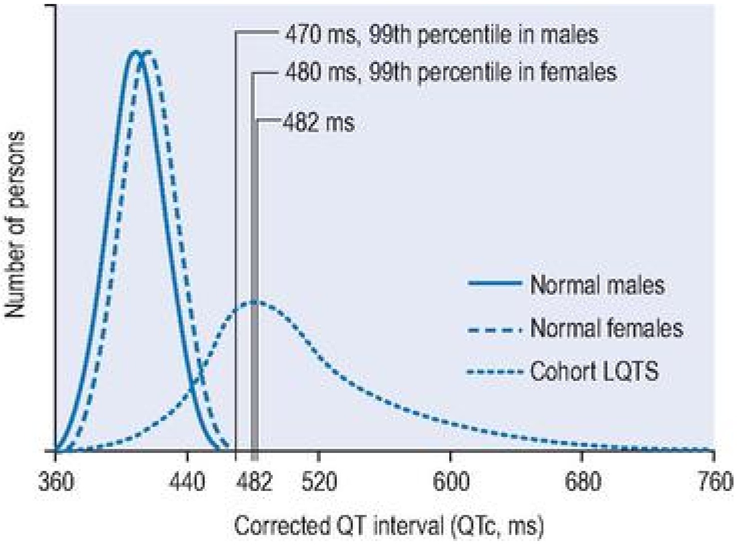
Long-qt syndrome [89, 90]

The traditional criteria of prolonged QT need to be corrected for heart rate (QT_c, Bazett's formula, QT divided by the square root of the RR interval) and a QT_c greater than 0.44 ms. Borderline QT_c is common and stems from miscalculation in the setting of atypical T-waves and prominent U-waves.[91] The recommended method to determine the end of the T-wave is by intersecting the tangent to the steepest slope of the last limb of the T-wave and the baseline (Fig. 31.52). The diagnosis of 'borderline LQTS' is common with QT_c in the range of 440–470 ms. QT_c should also be adjusted for age and gender with females an average 10 ms longer. There is significant overlap between the normal population and patients with congenital LQTS; 25%–35% of congenital LQTS have a QT_c <440 ms (Fig. 31.53).



The electrocardiogram traces present a single heartbeat cycle. Labels mark key components of the waveform. The P wave appears first, followed by the Q R S complex and then the T wave. A smaller U wave follows the T wave. An annotation labelled R R interval spans the distance between two consecutive peaks of the Q R S complex. Another annotation labelled Q T interval extends from the start of the Q R S complex to the end of the T wave. A dashed line connects the Q T interval to a formula at the bottom that reads Q T c equals Q T divided by the square root of R R. The tracing uses a standard grid layout typical for electrocardiogram recordings.

FIG. 31.52 Determining QTc using the ‘tangent method.’



The graph presents three distribution curves of corrected Q T intervals measured in milliseconds along the horizontal axis, ranging from 360 to 760 milliseconds. The vertical axis represents the number of persons. One curve represents normal males with a 99th percentile at 470 milliseconds. Another curve represents normal females with a 99th percentile at 480 milliseconds. A third curve represents a cohort with long Q T syndrome with a 99th percentile at 482 milliseconds. Labels above each curve indicate the respective 99th percentile values.

FIG. 31.53 Distribution of QTc values. 99th percentile males 470 ms. 99th percentile females 480 ms. There is significant overlap of these 'normal' QTc persons and a cohort of mutation-positive patients, mean QTc of 482 ms. (Adapted from Johnson JN, Ackerman M. QTc: how long is too long? *Br J Sports Med* . 2009;43:657–662; Taggart NW, Haglund CM, Tester DJ, et al. Diagnostic miscues in congenital long-QT syndrome. *Circulation* . 2007;115:2613–2620, with permission.)

The causes of LQTS can be divided into acquired and congenital (Box 31.7). Most drugs that cause LQTS do so by binding to the hERG or alpha subunit of the I_{Kr} potassium channel and reducing repolarisation current.

Unlike other I_K potassium channels, the hERG subunit of I_{Kr} is very sensitive to unintended drug binding owing to aromatic amino acids positioned in such a way as to block the channel. Common to all causes is a prolongation of repolarisation, which creates the substrate for random re-entry giving rise to polymorphous VT (classically of the torsade de pointes type), particularly under conditions of acute adrenergic arousal.

Box 31.7

Causes of long-QT syndrome

Acquired

- Drugs
    - Class IA antiarrhythmic drugs
    - Quinidine, procainamide
    - Class III antiarrhythmic drugs
    - Amiodarone, sotalol
    - Tricyclic antidepressants
    - Macrolide antibiotics
    - Phenothiazines
    - Antihistamines
    - Cisapride

- Myocardial ischaemia/infarction
- Hypokalaemia
- Cardiomyopathy
- Acute myocarditis
- Mitral valve prolapse
- Acute cerebral injury
- Hypothermia

Congenital

Familial

90%
Linked to a DNA marker on the short arm of chromosome 11
Autosomal-dominant in most cases
Some cases linked to congenital deafness and autosomal recessive

Non-familial – related to new gene mutation

Sporadic: 10%

AP prolongation results from either enhancing depolarisation (sodium [Na] channel, I_{Na}) or reducing repolarisation current (delayed rectifier potassium [K] currents, I_{Kr} and I_{Ks}).

There is less capacity to respond to additional stresses that impair repolarisation such as hypokalaemia, hypomagnesaemia and drugs with class III action.

Prolonged AP in LQTS predisposes to arrhythmia in two ways:

1. Extended plateau phase of AP results in susceptibility to EAD-initiated arrhythmia. EADs are due to re-opening of L-type calcium channels, the activity of which is increased by adrenergic stimulation, which explains the association between SCD and exercise and excitement in LQTS.
2. Heterogeneity of prolonged AP creates spatial dispersion of repolarisation, leading to regions of refractory block and substrate for re-entrant arrhythmia. This mechanism appears important in pharmacological LQTS.

Congenital LQTS [91]

Congenital LQTS is a collection of genetically distinct arrhythmogenic disorders resulting from genetic mutations in cardiac potassium and sodium ion channels giving rise to the term ‘cardiac channelopathies.’ As there is overlap in QT_c between the normal population and congenital LQTS patients, an LQTS clinical probability score has been developed to determine probability of diagnosis (Table 31.12).

Table 31.12

From Schwarlz PJ, Moss AJ, Vincent GM, Crampton RS. Diagnostic criteria for the long-QT syndrome. An update. *Circulation* . 1993; 88:782–784.

Congenital LQTS results from mutations in genes coding for cardiac proteins including ion channels, accessory subunits and modulatory proteins (Table 31.13).

Table 31.13

Classification of congenital LQTS

TYPE	GENE MUTATION/PROTEIN	FEATURES
LQT1	KCNQ1 α-subunit of I_{KS}	Reduced function of I_{KS} decreases repolarising current Most common at 30%–35% but less severe When homozygous associated with congenital deafness
LQT2	KCNH2/h ERG α-subunit of I_{Kr}	Reduced function of I_{Kr} decreases repolarising current 25%–30%
LQT3	SCN5A α-subunit of I_{Na}	Increased function of I_{Na} prolonging depolarising Na current Mutations in SCN5A also cause Brugada syndrome, cardiac conduction disease and dilated cardiomyopathy
LQT4	Anchor protein ankyrin B	Ankyrin B anchors ion channels in the cell
LQT5	KCNE1 β-subunit of I_{Ks}	Reduced function of I_{Ks} Homozygous leads to Jervell and Lange–Nielson syndrome Congenital deafness
LQT6	KCNE2 β-subunit of I_{Kr}	Reduced function of I_{Kr}
LQT7	K-channel I_{KI}	Anderson–Tawil syndrome Associated skeletal deformities

TYPE	GENE MUTATION/PROTEIN	FEATURES
LQT8	C_{AV} CACNAIc $I_{ca\text{-}L}$	Calcium channel is distributed widely Timothy's syndrome Multiple clinical manifestations

Clinical Features [92], [93]

Prevalence is estimated to be 1 in 2500–5000.

Thirty percent of patients with congenital LQTS present with unexplained syncope or aborted sudden death (which is often not the first episode). The majority (60%) are identified when family members are screened after syncope or cardiac arrest in a family member. Ten percent are detected on routine evaluation of ECG. The majority of episodes of syncope or sudden death (60%) are precipitated by emotions, physical activity or auditory stimuli causing acute adrenergic arousal. The degree of QT_c prolongation is not predictive of syncope or sudden death.

Management

The first line of management of polymorphous VT with shock is DC shock, with magnesium being the antiarrhythmic of choice.[94]

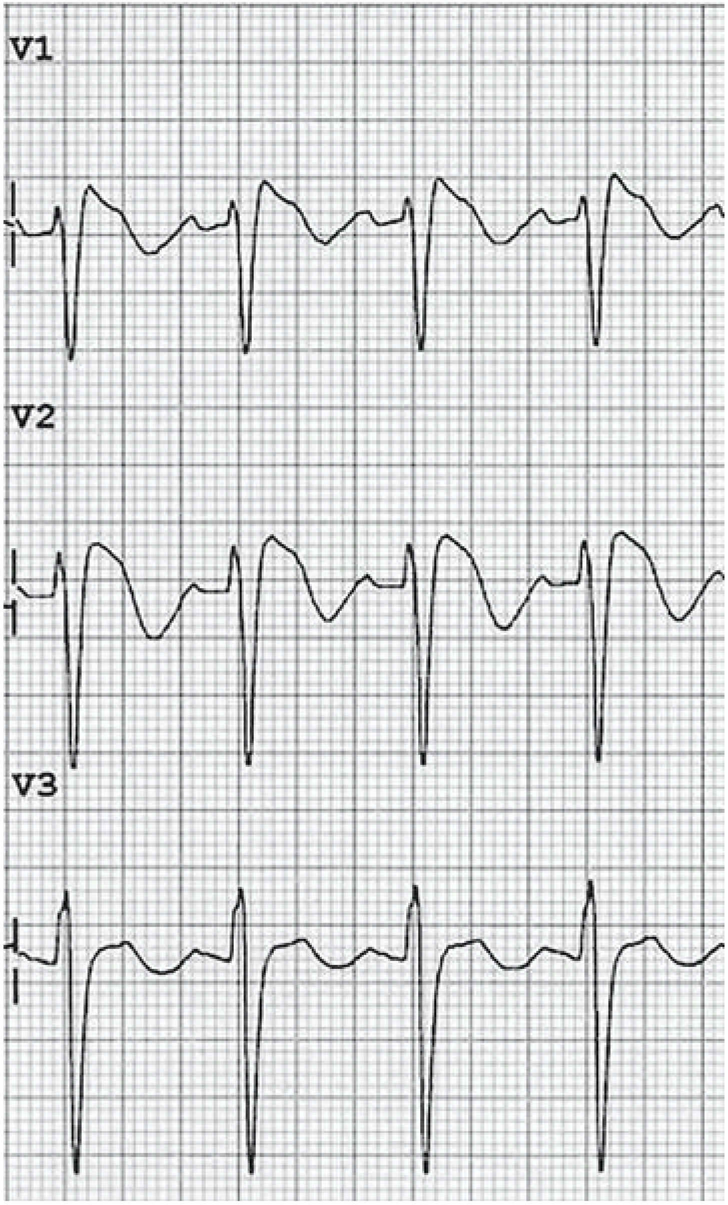
- Unresponsive rhythms or recurrence despite magnesium requires pharmacological intervention (isoproterenol [isoprenaline] or epinephrine [adrenaline] depending on blood pressure) or electrical pacing.
- Factors associated with acquired LQTS need to be identified and eliminated.

Strategies for prevention of recurrence in congenital LQTS depend on the presentation. Patients who present with or have a history of syncope or aborted sudden death have a high risk of recurrence (5% per year). Beta blockers are the first line of treatment with the goal of reducing the exercise heart rate to less than 130 beats/min. Symptomatic bradycardia following adequate beta blockade requires a permanent pacemaker. Patients with recurrence despite these measures and those with an early malignant course need stellate sympathetic ganglionectomy. In 5% of these high-risk patients, triple therapy fails and an implantable defibrillator is required. Asymptomatic patients with incidental LQTS (<0.5% per year) and asymptomatic family members (0.5% per year) have a very low risk of syncope or sudden death. It is also very rare for the first episode to be fatal in these two groups, so prophylactic measures are generally not required and close follow-up is sufficient.

Class IA, IC and III drugs may increase QT interval and should be avoided in polymorphous VT and torsade de pointes.

Brugada Syndrome

Is thought to be the underlying congenital channelopathy responsible for 20% of SCD due to polymorphic VT and/or VF in structurally normal hearts. The most common Brugada mutation involves the same gene as long-QT-3 syndrome, SCN5A which encodes the Na_v 1.5 channel. Other mutations have been identified affecting sodium, calcium and potassium channels. Re-entry between myocardial layers is the proposed mechanism. QTc is not prolonged and ECG changes facilitate diagnosis (Fig. 31.54). Provocation testing may be undertaken in patients where there is high clinical suspicion with atypical or intermittent ECG changes. Drugs such as flecainide or ajmaline are administered to enhance precordial ST elevation in a clinically suitable environment with comprehensive monitoring and resuscitation equipment, due to risk of precipitating ventricular arrhythmia.[93] ICD insertion helps prevent SCD.



The electrocardiogram consists of three traces. The first tracing labelled V 1 presents the electrical activity of the heart with a series of peaks and dips representing heartbeats. The second tracing, labelled V 2 follows a similar pattern but includes slight variations in the wave shapes. The third tracing, labelled V 3 exhibits a consistent rhythm with noticeable spikes at regular intervals. Each tracing captures multiple heartbeats over several seconds.

FIG. 31.54 Classic ECG findings Brugada Syndrome: ‘Coved’ ST elevation with type 1 morphology in precordial leads V1, V2 and V3 occurring spontaneously or after provocation with class I antiarrhythmic agents.

Sudden cardiac death[95]

Arrhythmic causes of SCD can be divided into three categories:

1. *VT or VF:* this is most common (see Table 31.14).
2. *SVT with a very rapid ventricular rate:* this is usually associated with the development of AF or flutter in the presence of an accessory AV connection (but can occasionally be due to enhanced conduction over the normal AV conduction system).
3. *Bradycardia or asystole:* this is usually the result of an inadequate escape pacemaker mechanism associated with either a high-degree AV block or severe SND. In addition, some patients with SND have paroxysmal supraventricular arrhythmia (tachycardia–bradycardia syndrome) that on termination results in an exaggerated overdrive suppression of both the sinus node and escape pacemakers such that the prolonged pause evolves into asystole or VF.

Table 31.14

ACS , acute coronary syndrome; *LVEF* , left ventricular ejection fraction; *VF* , ventricular fibrillation; *VT* , ventricular tachycardia.

The causes of these arrhythmias can be divided into three general categories:

1. *Ischaemic heart disease:* AMI or old myocardial infarction scar

2. *Non-ischaemic heart disease:* cardiomyopathy, valvular heart disease, congenital heart disease, ventricular hypertrophy and cardiac trauma
3. *No apparent structural heart disease:* primary electrical disease, electrolyte abnormalities, LQT syndromes and drugs.

Contributing factors are often multifactorial, particularly the combination of structural heart disease, proarrhythmic drugs and electrolyte abnormalities.

Evaluation of a Survivor of SCD

Primary prevention of SCD has been disappointing owing to difficulties in selecting patients at risk. Regardless of the aetiology of the SCD, the reported recurrence rate is high, at least 30%–40% at 1 year. Therefore in-hospital assessment is critical to establish the underlying cause and to guide therapy.

Coronary Artery Disease and Sudden Cardiac Death

Extensive atherosclerotic coronary artery disease is the most common pathological finding in survivors and non-survivors of SCD. Fewer than 30% have evidence of a recent AMI. A larger proportion (up to 50%) has evidence of coronary artery thrombosis or plaque fissuring and rupture. In those patients not having an AMI, the majority (75%) have a coronary artery stenosis (>50% of lumen), and 60% have three-vessel disease. Approximately 50% have evidence of an old myocardial infarction. The fact that the typical pathological background for SCD is severe epicardial coronary artery disease, with or without an old myocardial infarction and evidence of a new ischaemic syndrome, underlines the central role that coronary artery disease plays in SCD.

Investigations [18–20]

- *Chest X-ray:* cardiac size, presence of pulmonary oedema.
- *12-lead ECG:* acute ischaemia, previous infarction, ventricular aneurysm or LV hypertrophy. Abnormalities of rate, rhythm, conduction or SND. PR interval, QRS complex duration or QT interval. Changes of electrolyte abnormalities.
- *Plasma electrolytes:* potassium, magnesium and calcium. Potassium levels may be difficult to interpret after a period of resuscitation.
- *Cardiac enzymes:* serial troponin T, creatinine phosphokinase with myocardial band fractionation and lactate dehydrogenase to establish the presence of a recent AMI.
- *Plasma blood levels of drugs that affect cardiac rhythm or conduction:* while proarrhythmic effects of drugs are more likely at high levels, it should be emphasised that proarrhythmia can occur at normal or low plasma drug levels.
- *Toxicology screen:* substance abuse or drug overdose (cocaine, psychotropic drugs), particularly in patients without overt structural heart disease.
- *24-hour Holter monitor ECG:* quantitative analysis of frequency of arrhythmia and to detect silent myocardial ischaemia.
- *Assessment of LV function:* LV ejection fraction. Gated pool scan gives a better estimate of global LV systolic function, but echocardiogram will give added diagnostic information such as valvular disease and myocardial hypertrophy. Both studies will detect segmental wall motion abnormalities.
- *Exercise tolerance test:* standard exercise ECG or thallium-201 scans. Echocardiogram immediately following exercise may be as informative.
- *Signal-average ECG:* averages between 100 and 400 heart beats, for identification of low-amplitude electrical signals, such as after-depolarisations. These are found in the terminal portion of the QRS complex and cannot be seen on the 12-lead ECG. Associated with an increased risk of spontaneous and inducible ventricular arrhythmia.
- *Cardiac catheterisation and coronary angiogram:* to quantify the degree of coronary artery disease.

- *EPS:* virtually always indicated to document and characterise ventricular tachyarrhythmia. The initial baseline EPS should be performed in the absence of any antiarrhythmic drugs. Inducibility of sustained ventricular arrhythmias at EPS is associated with worse outlook, with a 5-year risk of SCD of 32% versus 24% in those without inducible arrhythmia, and is an indication for an implantable defibrillator. The inducibility of VT/VF is less common in survivors of SCD (44%) than in patients who present with recurrent sustained VT. In patients with sustained monomorphic haemodynamically stable VT, EPS mapping techniques are used to determine the possibility of surgical or catheter ablation. EPS is also important in other causes of SCD other than VT/VF. Patients with ventricular pre-excitation (WPW syndrome) require localisation of the accessory pathway. Propensity to develop complete heart block can be assessed by a His-bundle ECG.

Prevention of Recurrent Ventricular Arrhythmia in Survivors of Sudden Cardiac Death

Myocardial Revascularisation and Sudden Cardiac Death

The Coronary Artery Surgery Study (CASS) registry looked at 13,476 patients with significant operable coronary artery disease and showed an incidence of SCD of 5.2% in the medical arm compared with 1.8% in those assigned to surgery. [96] The precise mechanism of the benefit of surgery in primary prevention is unclear but is probably associated with prevention of ischaemia rather than arrhythmia control. In summary, the near-universal practice of surgical coronary revascularisation in SCD survivors with critical stenoses is based upon this primary prevention data (and the central role that ischaemia and infarction are known to play in arrhythmia substrate) rather than data demonstrating arrhythmia control.

Antiarrhythmic Drugs and Sudden Cardiac Death [77–80]

The CAST study has clearly demonstrated the poor results of antiarrhythmic drug therapy alone in the prevention of arrhythmic SCD. Data from studies in survivors of SCD using amiodarone are conflicting, but generally poor, even with EPS confirmation of lack of inducibility. Certainly, patients with an ejection fraction of less than 30% do poorly on amiodarone alone. The primary role of antiarrhythmic drugs in the secondary prevention of SCD has all but disappeared, but amiodarone may be indicated if there is demonstrable suppression of inducible VT at EPS and the patient has an ejection fraction greater than 30%–40%.

Surgical and Catheter Ablation Techniques and Sudden Cardiac Death [27]

As most sustained ventricular arrhythmias arise from a scar within the myocardium, surgical attempts were made to excise these areas completely. Catheter ablation techniques for VT are suitable for the minority of patients with haemodynamically stable VT who can withstand prolonged mapping procedures. Currently, the success rates for ablative techniques are such that a significant number still need additional preventive therapies.

Implantable Cardioverter Defibrillators and Sudden Cardiac Death

The reduction in SCD and overall cardiac mortality with ICDs has been so spectacular and the results of previous therapies so poor that ICDs were initially introduced with little randomised controlled data. More recently controlled studies have shown:

- reduction in 3-year mortality by 31% compared to antiarrhythmic drug therapy in SCD survivors [97]
- reduced risk of death in patients with poor LV function following myocardial infarction [98]
- improved survival in patients with HCM. [99]

However, no survival benefit was shown in high-risk patients following coronary artery bypass surgery.

Representative data from several studies are shown in Table 31.15 . The benefit of ICD on survival persists for at least 8 years. Current indications are expanding, but the benefit is clear in the following groups of survivors of SCD and patients with documented VT/VF outside the early post-infarct phase:

- non-inducible VT/VF at EPS
- inducible VT/VF resistant to treatment
- VT/VF in patients with LV ejection fractions less than or equal to 30% regardless of results of EPS-directed drug therapy.

Table 31.15

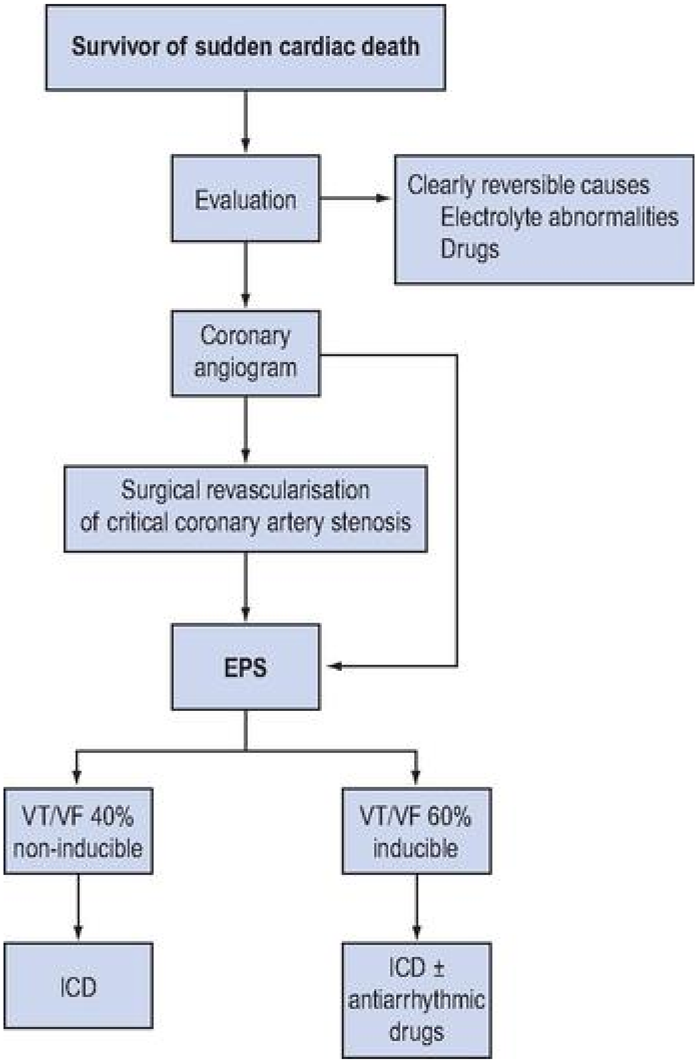
Mortality data for the various treatment regimens for sudden cardiac death

	SUDDEN DEATH (%)	TOTAL MORTALITY (%)
Implantable cardioverter defibrillator	3.5	13.6
Empirical amiodarone	12	34
Electrophysiological study-directed drug treatment	14	24
Surgery	3.7	37

Further developments currently taking place include:

- transvenous catheter placement and subcutaneous patch avoiding the need for thoracotomy
- dual-chamber sensing to improve discrimination between SVT and VT that can be difficult on rate criteria alone, particularly in patients with intraventricular conduction delay
- technological advances reducing size, cost and increasing battery life.

Although one of the proposed advantages of ICD is the avoidance of antiarrhythmic drug side effects, particularly the myocardial depressant effects, current practice usually combines ICD with low-dose amiodarone. This enables improved arrhythmia control by reducing atrial tachyarrhythmia and slowing VT rate, and prolonging battery life by reducing the frequency of arrhythmia. The role of ICD in the management algorithms of SCD is shown in Figs. 31.55 and 31.56 . Given the current lack of available ICDs, some advocate restrictions for patients less than 75 years. With wider availability of ICDs, fewer patients will be managed on drug-only strategies in the future.



Survivor of sudden cardiac death
Evaluation
Clearly reversible causes

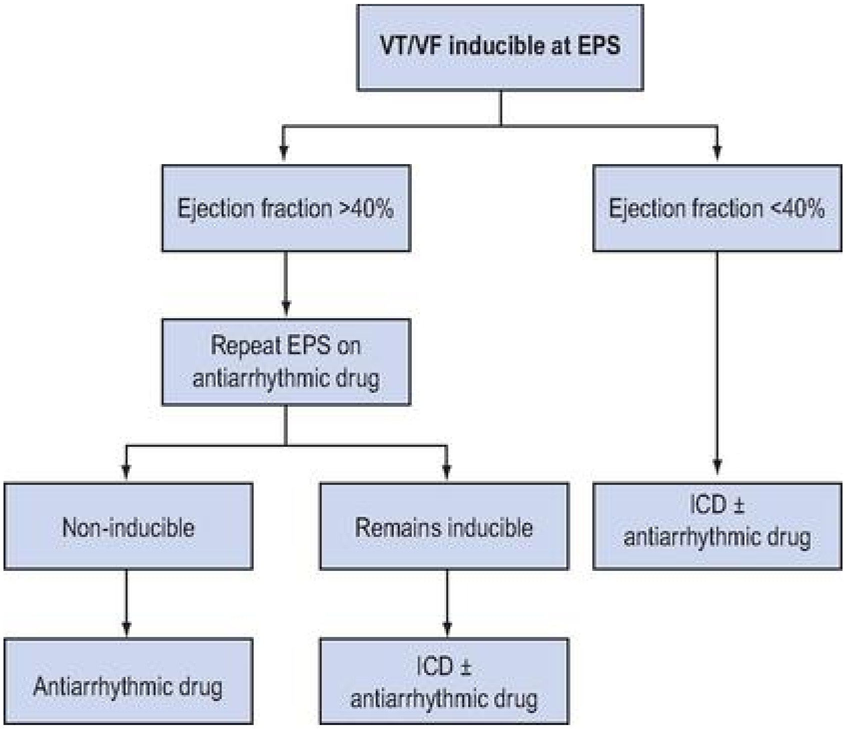
ICD ± antiarrhythmic drugs

The flowchart outlines the evaluation process for survivors of sudden cardiac death. It begins with a box labelled evaluation. An arrow from this box points to a box labelled coronary angiogram. Another arrow from the evaluation box points to a box labelled electrophysiological study. From the electrophysiological study box two arrows lead to different outcomes. One arrow points to a box labelled ventricular tachycardia or ventricular fibrillation, 40 percent non-inducible. The other arrow points to a box labelled ventricular tachycardia or ventricular fibrillation, 80 percent inducible. From the non-inducible box, an arrow points to a box labelled implantable cardioverter defibrillator. From the inducible box, an arrow points to a box labelled implantable cardioverter defibrillator and antiarrhythmic drug. An additional note near the evaluation box states clearly reversible causes drug.

FIG. 31.55 Management algorithm of a survivor of sudden cardiac death. This algorithm does not include the option of an antiarrhythmic drug alone in patients with intact left ventricular function who initially have inducible ventricular tachycardia/fibrillation *(VT/VF)* that is subsequently found to be suppressible on a drug with electrophysiological studies *(EPS)* . *ICD* , Implantable cardioverter defibrillator.



VT/VF inducible at EPS
Ejection fraction >40%
Ejection fraction <40%
Repeat EPS on antiarrhythmic drug
Non-inducible
Remains inducible
ICD ± antiarrhythmic drug
Antiarrhythmic drug
ICD ± antiarrhythmic drug

The flowchart addresses the management of ventricular tachycardia or ventricular fibrillation inducible at electrophysiological study. It starts with a box labelled ventricular tachycardia or ventricular fibrillation inducible at electrophysiological study. Two arrows from this box point to two separate paths based on ejection fraction. The first path labelled ejection fraction greater than 40 percent leads to a box labelled repeat electrophysiological study on antiarrhythmic drug. From this box, two arrows point to outcomes. One arrow leads to a box labelled non-inducible and then to a box labelled antiarrhythmic drug. The other arrow leads to a box labelled remains inducible and then to a box labelled implantable cardioverter defibrillator and antiarrhythmic drug. The second path, labelled ejection fraction less than 40 percent, leads directly to a box labelled implantable cardioverter defibrillator and antiarrhythmic drug.

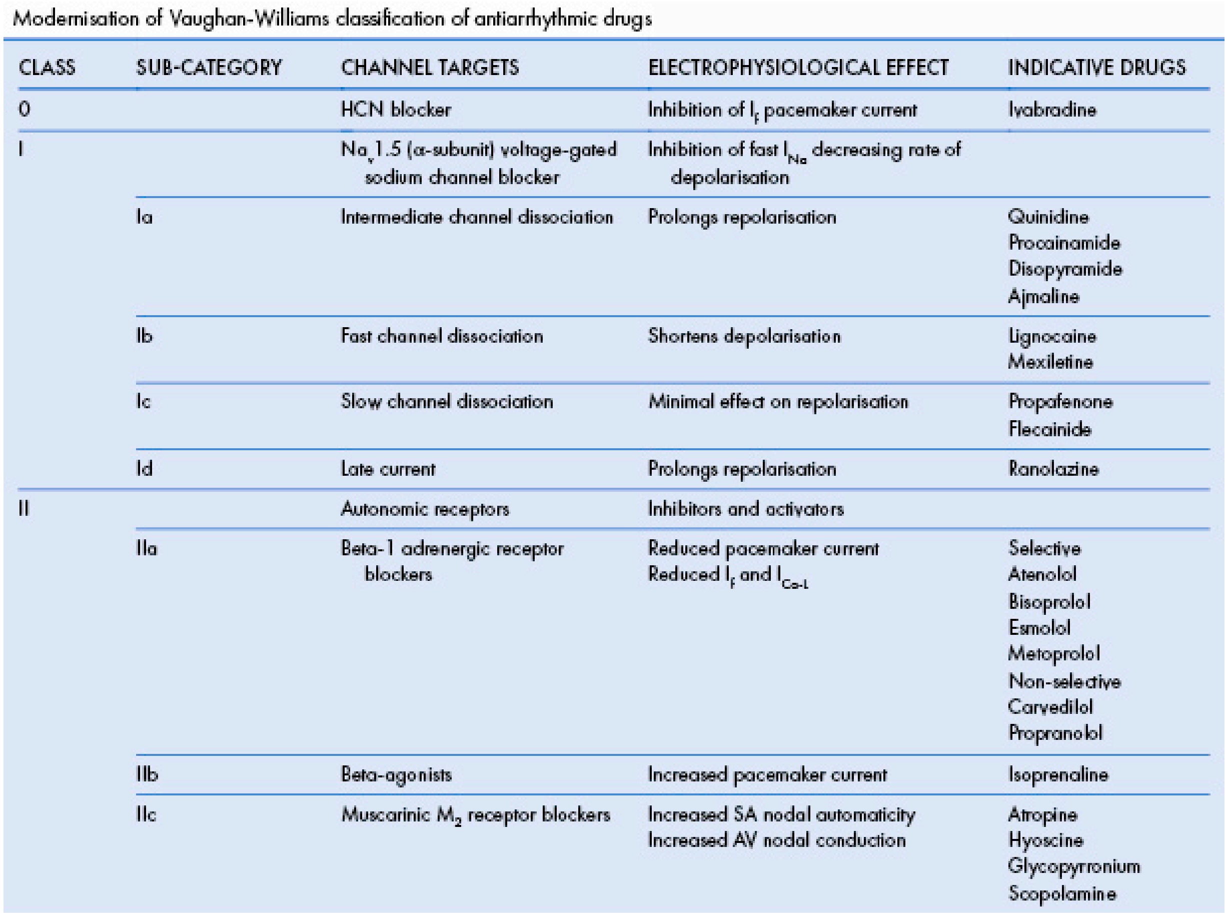
FIG. 31.56 Patients found to have inducible ventricular tachycardia (VT) or fibrillation (VF) at electrophysiological studies (EPS), with an ejection fraction >40% and subsequent drug suppression of their VT/VF, can be managed on antiarrhythmic drugs alone.

Classification of Antiarrhythmic Drugs

The time-honoured physiologically based classification of antiarrhythmic drugs is the Vaughan-Williams classification. This classification is a hybrid, with classes I and IV representing ion channel blockers, class II representing a receptor blocker and class III representing a change in an electrophysiological variable. Class I drugs (phase 0 sodium channel blockers) have variable receptor affinity, with slow binding and dissociation of class Ic agents correlating with anti- and proarrhythmogenic actions. Flecainide (Class Ic) has high proarrhythmic effects with the least effect on repolarisation of class I agents due to lowest I_K effect. Prolongation of repolarisation, the defining effect of class III agents, can be produced by a block of any one of several K+ ionic channels (the delayed rectifier potassium current I_{Kr} responsible for phase 3 repolarisation is the ionic channel target of most class III agents) or from modification of Na+ or Ca+ channel function. The classification is incomplete and does not include cholinergic agonists, digitalis, magnesium and adenosine.

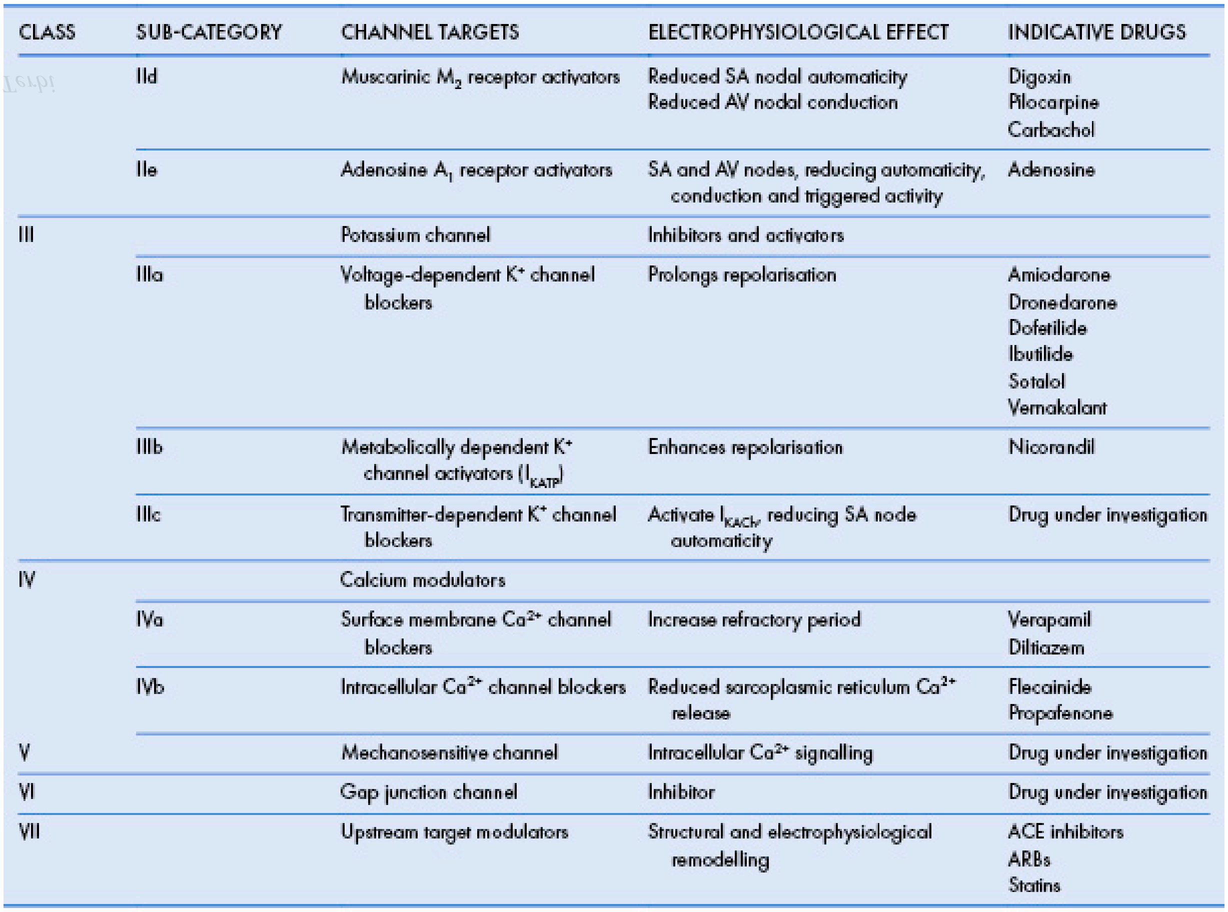
With an eye on the future, the Vaughan-Williams has recently undergone modernisation to provide a more comprehensive classification system of antiarrhythmic drugs based on electrophysiological actions (Table 31.16).[100] In addition to expanding classes I-IV, new classes include hyperpolarisation-activated cyclic nucleotide-gated (HCN) channel blockers (Class 0; acting on sino-atrial automaticity), mechanosensitive channel blockers (Class V; future target acting when the myocardium is subject to volume or pressure load), gap junction channel blockers (Class VI; future target blocking gap junction conductance or expression) and upstream target modulators (Class VII; targeting cardiac structural remodelling, e.g. angiotensin-converting enzyme inhibitors).

Table 31.16



Modernisation of Vaughan-Williams classification of antiarrhythmic drugs

CLASS	SUB-CATEGORY	CHANNEL TARGETS	ELECTROPHYSIOLOGICAL EFFECT	INDICATIVE DRUGS
0		HCN blocker	Inhibition of I_f pacemaker current	Ivabradine
I		$Na_v1.5$ (α-subunit) voltage-gated sodium channel blocker	Inhibition of fast I_{Na} decreasing rate of depolarisation	
	Ia	Intermediate channel dissociation	Prolongs repolarisation	Quinidine Procainamide Disopyramide Ajmaline
	Ib	Fast channel dissociation	Shortens depolarisation	Lignocaine Mexiletine
	Ic	Slow channel dissociation	Minimal effect on repolarisation	Propafenone Flecainide
	Id	Late current	Prolongs repolarisation	Ranolazine
II		Autonomic receptors	Inhibitors and activators	
	IIa	Beta-1 adrenergic receptor blockers	Reduced pacemaker current Reduced I_f and I_{Ca-L}	Selective Atenolol Bisoprolol Esmolol Metoprolol Non-selective Carvedilol Propranolol
	IIb	Beta-agonists	Increased pacemaker current	Isoprenaline
	IIc	Muscarinic M_2 receptor blockers	Increased SA nodal automaticity Increased AV nodal conduction	Atropine Hyoscine Glycopyrronium Scopolamine



CLASS	SUB-CATEGORY	CHANNEL TARGETS	ELECTROPHYSIOLOGICAL EFFECT	INDICATIVE DRUGS
	IId	Muscarinic M_2 receptor activators	Reduced SA nodal automaticity Reduced AV nodal conduction	Digoxin Pilocarpine Carbachol
	IIe	Adenosine A_1 receptor activators	SA and AV nodes, reducing automaticity, conduction and triggered activity	Adenosine
III		Potassium channel	Inhibitors and activators	
	IIIa	Voltage-dependent K^+ channel blockers	Prolongs repolarisation	Amiodarone Dronedarone Dofetilide Ibutilide Sotalol Vernakalant
	IIIb	Metabolically dependent K^+ channel activators (I_{KATP})	Enhances repolarisation	Nicorandil
	IIIc	Transmitter-dependent K^+ channel blockers	Activate I_{KACh}, reducing SA node automaticity	Drug under investigation
IV		Calcium modulators		
	IVa	Surface membrane Ca^{2+} channel blockers	Increase refractory period	Verapamil Diltiazem
	IVb	Intracellular Ca^{2+} channel blockers	Reduced sarcoplasmic reticulum Ca^{2+} release	Flecainide Propafenone
V		Mechanosensitive channel	Intracellular Ca^{2+} signalling	Drug under investigation
VI		Gap junction channel	Inhibitor	Drug under investigation
VII		Upstream target modulators	Structural and electrophysiological remodelling	ACE inhibitors ARBs Statins

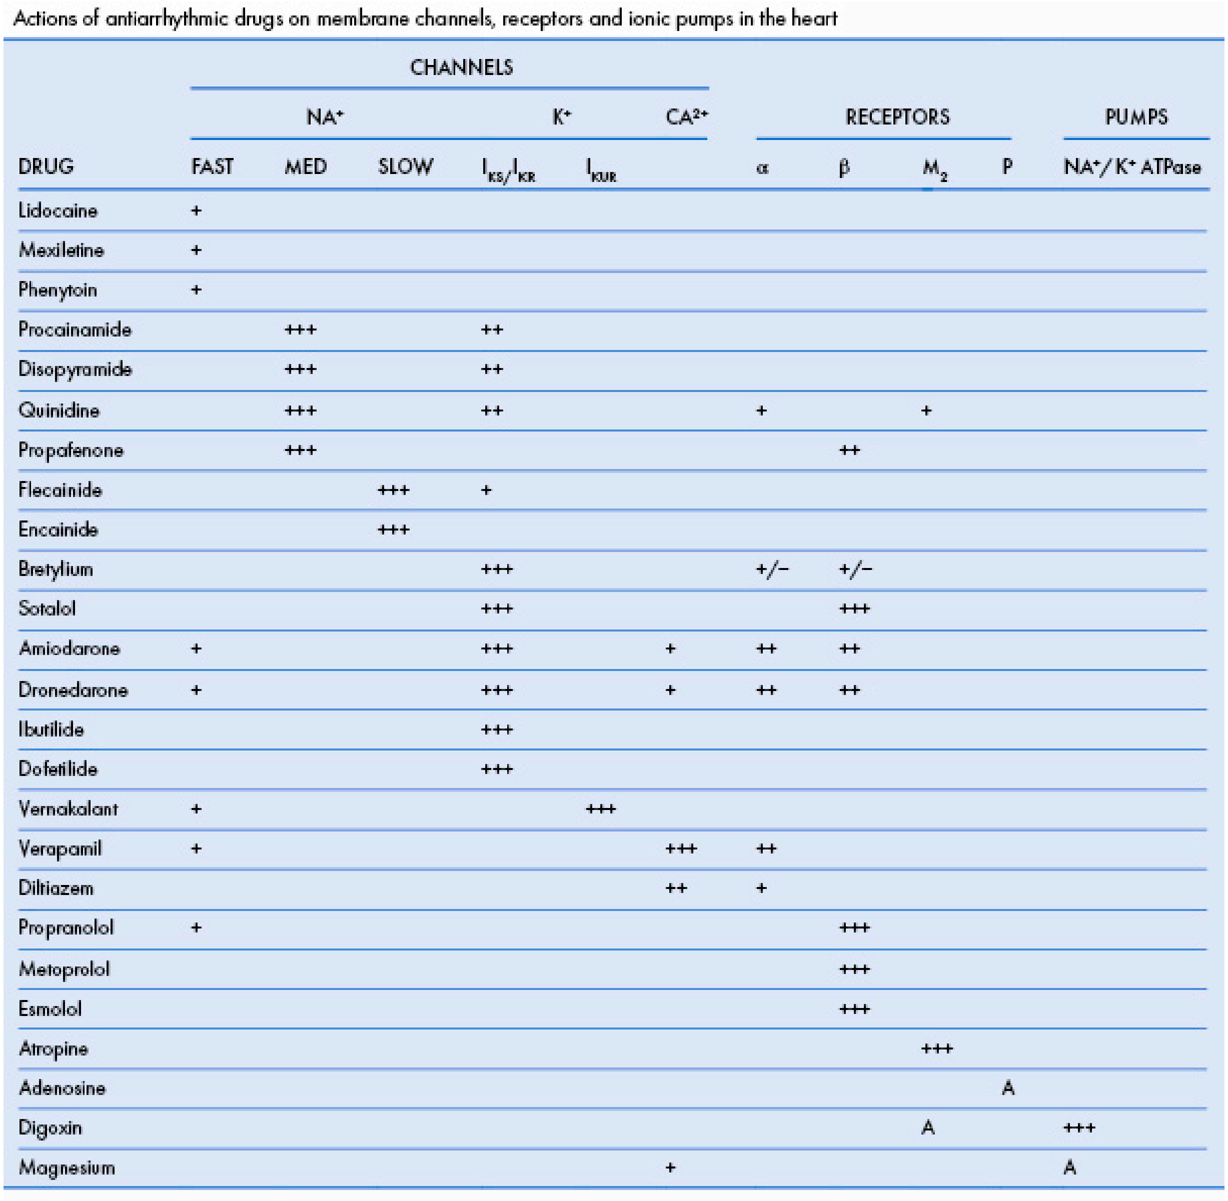
---

ACE , Angiotensin-converting enzyme; *ARB* , angiotensin receptor blocker; *AV* , atrioventricular; *HCN* , hyperpolarisation-activated cyclic nucleotide-gated; *SA* , sinoatrial.

Adapted from Lei M, Wu L, Terrar DA, et al. Modernized classification of cardiac antiarrhythmic drugs. Circulation. 2018;138:1879-1896.

An alternative classification has also been advocated based on molecular targets for drug action that include ion channels, receptors and pumps/carriers (Table 31.17). [4]

Table 31.17



Actions of antiarrhythmic drugs on membrane channels, receptors and ionic pumps in the heart

	CHANNELS						RECEPTORS				PUMPS
	NA⁺			K⁺		CA²⁺					
DRUG	FAST	MED	SLOW	I_{KS}/I_{KR}	I_{KUR}		α	β	M_2	P	NA⁺/K⁺ ATPase

Digoxin									A		+++
Magnesium						+					A

Sodium channel blockers are subdivided into drugs with fast-, medium- and slow-time constant for recovery from block. Receptors: α-, β-adrenoreceptors, *M_2* , muscarinic subtype 2; *P* , A_1 purinergic. Relative blocking potency: +, low; ++, moderate; +++, high; +/− , partial agonist/antagonist; *A* , agonist.

Antiarrhythmic drugs

Digoxin

Digoxin is a muscarinic subtype 2 receptor (M_2) agonist and a highly potent Na^+/K^+-ATPase pump-blocking agent. Digoxin exerts its antiarrhythmic activity predominantly at the AV node where at lower doses conduction is slowed by the M_2 vagotonic effect. This effect is easily reversed by enhanced sympathetic tone in the setting of exercise, critical illness and postoperative state. At higher concentrations, digoxin has a direct effect on AV node conduction by the Na^+/K^+-ATPase pump blockade and is more resistant to sympathomimetic effects. The decrease in $[K^+]_i$ and increase in $[Na^+]_i$ results in hyperpolarisation, shortening of atrial AP and an increase in AV nodal refractoriness. There is also increased availability of intracellular Na^+ for the Na^+–Ca^{2+} exchanger, increasing $[Ca^{2+}]_i$ which results in the positive inotropic effects of digoxin, making it an ideal agent in the setting of LV dysfunction. However, the positive inotropic effects of Na^+/K^+-ATPase blockade are deleterious in the setting of myocardial ischaemia and other causes of diastolic dysfunction. Digoxin also has weak vasopressor properties when administered as a slow bolus. The major ECG effects of digoxin are PR prolongation and a non-specific alteration in ventricular repolarisation with characteristic reverse-tick S-T segments.

Indications and Dose

- *AF:* slowing of ventricular rate only
- *Loading dose:* 15 µg/kg IV in 2-3 divided doses over 24 hours, typically administered over 30–60 minutes, but can be given faster
- *Maintenance dose:* depends on renal function.

Plasma Levels

Oral bioavailability can be reduced, especially if intestinal microflora-altering antibiotics are co-administered. Therapeutic levels are 0.5–

2.0 ng/mL. Plasma levels must be measured during the post-distribution phase some 6–8 hours after dose. The elimination half-life is 36 hours with normal renal function. Difference between therapeutic and toxic levels can be reduced by hypokalaemia, hypomagnesaemia, hypercalcaemia, hypoxia, cardiac surgery and myocardial ischaemia. Many drugs increase digoxin plasma levels by competing with the renal P-glycoprotein-mediated transport, or by reducing renal blood flow or function.

Contraindications

Relative contraindications include myocardial ischaemia/infarction, diastolic heart failure due to hypertrophy and ischaemia, renal failure and hyperkalaemia, planned DC shock cardioversion and tachycardia–bradycardia syndromes. Co-administration with other drugs that affect AV nodal conduction, typically beta-adrenergic and calcium channel blockers, requires caution.

Adverse Effects

The same increase in $[Ca]_i$ responsible for the positive inotropic effects of digoxin also forms the basis for toxicity arrhythmia. The increased inward calcium current is responsible for DAD-initiated arrhythmia. Digoxin toxicity can cause virtually any arrhythmia:

- DAD-related tachycardia with impairment of sinus node or AV nodal function
- unifocal atrial tachycardia with AV block is ‘classic’
- ventricular bigeminy and various degrees of AV block occur.

With advanced toxicity, severe hyperkalaemia due to poisoning of Na^+/K^+-ATPase results. Profound bradycardia, which may be unresponsive to pacing, develops.

Any serious toxicity arrhythmia should be treated with antidigoxin Fab fragments. Magnesium is the drug of choice for digoxin-toxic tachyarrhythmia. Digoxin, particularly at toxic levels, increases risk of VF precipitated by DC shock. Digoxin toxicity is associated with nausea, disturbances in cognitive function and blurred or yellow vision (xanthopsia).

Beta-Adrenergic Blockers

Beta-adrenergic blocking or class II antiarrhythmic drugs have differing properties such as relative cardioselectivity (atenolol, metoprolol), non-cardioselectivity (propranolol), intrinsic sympathomimetic activity (pindolol), lipid solubility and central activity (metoprolol, propranolol) and membrane-depressant effects (propranolol). The antiarrhythmic properties appear to be a class effect and no agent has been shown to be superior. There are data to suggest that the survival benefit of beta-adrenergic blockers post-myocardial infarction may relate to some extent to the central modulation of autonomic tone of the more lipid-soluble agents. The direct membrane-stabilising or ‘quinidine-like’ effect of propranolol requires doses far greater than those used clinically and is of negligible clinical significance. Beta-adrenergic blockers competitively inhibit catecholamine binding at the beta-adrenergic receptor sites, which reduces the phase 4 slope of the AP of pacemaker cells, prolongs their refractoriness and slows conduction in the AV node. Refractoriness and conduction in the His–Purkinje system are unchanged. Beta-adrenergic blockers are most effective in arrhythmia associated with increased cardiac adrenergic stimulation (postoperative states, sepsis, thyrotoxicosis, phaeochromocytoma, exercise or emotion).

Indications

Supraventricular Tachycardia

Beta-adrenergic blockers may terminate SVT when the AV node is an intrinsic part of the re-entry circuit (AVNRT and AVRT); adenosine is more effective. AF and Afl do not revert with beta-adrenergic blockers, but the ventricular rate will be slowed. Beta-adrenergic blockers are effective at preventing SVT following cardiac surgery. Studies involving propranolol and atenolol have produced the best results. Beta-adrenergic blockers are effective in MAT, but, as this arrhythmia is most often seen in patients with severe chronic air-flow limitation and cor pulmonale, their utility is limited.

Ventricular Arrhythmias

Beta-adrenergic blockers are ineffective for the emergency treatment of sustained VT. Empiric prophylactic administration of beta-adrenergic blockers appears to be as effective in ventricular arrhythmia prevention as electrophysiologically guided drug methods. However, ventricular arrhythmia most often occurs in the setting of poor LV dysfunction and beta-adrenergic blockers are either poorly tolerated or contraindicated.

Myocardial Infarction

Survival in patients with AMI treated with thrombolytic therapy is improved by early IV beta-adrenergic blockade. Presumably, this will remain the same with the current strategy of percutaneous coronary intervention. There may be other benefits such as decreased incidence of VF and relief of chest pain. Long-term beta-adrenergic blockade reduces mortality following myocardial infarction, the benefit being greatest in those at highest risk for sudden death. However, suppression of ventricular ectopy is not a requisite for benefit. Drugs with intrinsic sympathomimetic activity have not been shown to improve survival after AMI.

Atenolol

Atenolol does not have significant central action due to poor lipid solubility and is eliminated predominantly by the kidneys with an elimination half-life of 7–9 hours. Care is required in patients with poor or deteriorating renal function.

- *Loading dose IV:* 2.5 mg over 2.5 minutes, repeat every 5 minutes, maximum 10 mg
- *Loading dose oral:* 50–100 mg
- *Maintenance dose oral:* 50–200 mg/day

Metoprolol

Metoprolol is lipid-soluble and has significant central action. It is eliminated by the liver with an elimination half-life of 3–4 hours.

- *Loading dose IV:* 1–2 mg at 1 mg/minute, repeat every 5 minutes, maximum dose 15–20 mg
- *Loading dose oral:* 100–200 mg
- *Maintenance dose oral:* 50–100 mg/12-hourly.

Propranolol

Propranolol has been one of the most studied beta-adrenergic blockers for SVT prophylaxis following cardiac surgery.

- *Dose:* 10 mg orally 6-hourly starting the morning after surgery.

Esmolol

Esmolol is an ultrashort-acting cardioselective beta-adrenergic blocker, which is especially useful for rapid control of ventricular rate in AF or Afl. Esmolol has also been shown to prevent postoperative SVT. The distribution half-life is 2 minutes and the elimination half-life is 9 minutes. Esmolol is rapidly metabolised by hydrolysis of the ester linkage, chiefly by the esterases in the cytosol of red blood cells and not by plasma cholinesterases or red cell membrane acetyl-cholinesterase:

- *Loading dose IV:* 500 µg/kg over 1 minute
- *Maintenance dose IV:* 50 µg/kg per minute for 4 minutes. If satisfactory rate control is not achieved, the loading dose should be repeated and the maintenance dose increased to 100 µg/kg per minute. If control is still not achieved after a further 4 minutes, then the procedure is repeated with 50 µg/kg per minute increments in the maintenance infusion until maximum dose of 200 µg/kg per minute is reached. Further increases in infusion rate are unlikely to be successful.

Contraindications

Reversible airway disease and poor LV function are two common relative contraindications, which limit the utility of beta-adrenergic blockers in patients with cardiac disease. Beta-adrenergic blockers may also be poorly tolerated in diabetics and patients with severe peripheral vascular disease.

Adverse Effects

Beta-adrenergic blockers, particularly those that are centrally acting, are often poorly tolerated in the long term. These effects include fatigue, hypotension, bradycardia, dry mouth, dizziness, headache and cold extremities.

Calcium Channel Blockers

Calcium channel blockers or class IV antiarrhythmic drugs block the slow calcium channels in cardiac tissue. Verapamil and diltiazem have similar electrophysiological properties. The dihydropyridine group of calcium channel blockers, which include nifedipine, does not have any significant electrophysiological properties. Calcium channel blockers depress the slope of diastolic depolarisation in the SA node cells, the rate of rise of phase 0 and AP amplitude in the SA and AV nodal cells. They also slow conduction and prolong the refractory period of the AV node, which results in their main antiarrhythmic actions. Refractoriness of atrial, ventricular and accessory pathway tissue is unchanged. The sinus rate does not usually change significantly because calcium channel blockers induce peripheral vasodilatation, which causes reflex sympathetic stimulation of SA node. Verapamil particularly has marked negative inotropic actions and hypotension is often seen; however, cardiac index is generally maintained because of afterload reduction. Diltiazem has a less negative inotropic effect than verapamil.

Indications

- *SVT:* calcium channel blockers are effective if the AV node is an integral part of the arrhythmia circuit. Verapamil has been superseded by adenosine for the first line of treatment for these with AVNRT and AVRT
- *AF and Afl:* slow ventricular response in AF and Afl, but termination of the arrhythmia is uncommon. Verapamil may

prolong episodes of AF through a proarrhythmic effect

- *MAT:* calcium channel blockers are effective [31]
- *SVT following cardiac surgery:* diltiazem has been shown not only to reduce but also to decrease incidence of ventricular arrhythmia and postoperative ischaemia
- *AF associated with the WPW syndrome:* calcium channel blockers may increase the ventricular response and should be avoided if this is suspected. [28]

In general, calcium channel blockers should not be given to patients with wide-complex tachycardia not only because of the risk of accelerating accessory pathway conduction but also because their myocardial depressant effects can result in cardiovascular collapse in the setting of VT and pre-existing myocardial dysfunction.

Verapamil

Verapamil is cleared by the liver with an elimination half-life of 3–8 hours. Therapeutic plasma concentration is 0.1–0.15 mg/L. With the availability of adenosine and the better tolerance of diltiazem, the use of verapamil has fallen substantially:

- *Loading dose IV:* 5–10 mg, maximum 0.15 mg/kg over 2 minutes. If poor response after 30 minutes repeat dose of up to 10 mg, 0.15 mg/kg to a maximum of 20 mg.
- *Maintenance dose IV:* infusion up to 10 mg/hour titrated to effect.
- *Maintenance dose oral:* 80–120 mg 6–8-hourly.

Diltiazem

Diltiazem is cleared by the liver with an elimination half-life of 3.5 hours. There is reduced oral absorption and extensive first-pass hepatic metabolism: only 40% of oral dose is available compared with IV:

- *Loading dose IV:* 0.25 mg/kg, followed by 0.35 mg/kg if required
- *Maintenance dose IV:* infusion up to 10 mg/hour titrated to effect

- *Maintenance dose oral:* 60–120 mg 6–8-hourly
- *SVT prophylaxis following cardiac surgery:* 0.1 mg/kg per hour, starting at onset of bypass and continuing for 24 hours. The dose can be titrated up for blood pressure control.

Magnesium

Magnesium is an antiarrhythmic agent with a range of indications, however, as an antiarrhythmic agent, magnesium has largely defied classification. Magnesium has many reported electrophysiological effects, including blocking voltage-dependent L-type Ca^{2+} channels. Magnesium is a necessary cofactor for the membrane enzyme Na^{+}/K^{+}-ATPase that provides energy for the membrane Na/K channels.[101] Consequences of magnesium deficiency are as follows:

- Intracellular potassium falls and intracellular sodium rises, leading to a reduction in RMP.
- Intracellular sodium is elevated, increasing the availability of sodium for the Na/Ca counter-transport mechanism.
- The resulting elevation in intracellular calcium predisposes to DAD-triggered activity.

Magnesium administration reduces the availability of intracellular Na^{+} and therefore this Ca^{2+} inward current. The dependency of normal membrane potassium gradients on magnesium is demonstrated by the inability to correct intracellular potassium deficiency with the administration of potassium in the setting of hypomagnesaemia. The antiarrhythmic properties of supranormal levels of magnesium associated with pharmacological doses of magnesium appear to be largely due to augmentation of this physiological role of magnesium. Therefore magnesium may be best classified as a Na/K pump agonist.

Magnesium in pharmacological doses decreases RMP, resulting in a reduction in automaticity. However, once depolarisation occurs, the maximum rate of depolarisation and AP amplitude is increased, thereby improving conduction. AP duration is increased, thereby increasing the absolute refractory period and reducing relative refractory period. The net result is a reduction in the vulnerable period and more synchronous conduction. All of these electrophysiological effects are augmented in the setting of increased extracellular potassium. It is not surprising that the utility of magnesium appears greatest in the setting of ischaemia where loss of potassium from the cell is a major consequence. A secondary effect is the reduction in the availability of intracellular sodium to contribute to inward calcium flux, producing triggered activity. Magnesium has also been shown to elevate VF and ectopy threshold. [102]

Indications

- Acute rate control of AF, and has been shown to be as effective as amiodarone in the short term. [71]
- Prevent postoperative SVT following cardiac surgery with varying efficacy.
- Acute control of MAT.
- Ventricular arrhythmia associated with triggered activity, such as torsade de pointes and digoxin toxicity. [94]
- Drug-induced polymorphous VT, particularly that caused by class I agents, can also be terminated with magnesium.
- Appears very effective at controlling transient ventricular arrhythmia in the setting of ischaemia such as post-infarct and cardiac surgery.

Dose

- *AF rate and MAT control:* magnesium sulphate, 0.15 mmol/kg, in an adult 10–20 mmol (2.5–5.0 g) over 5–10 minutes. If no response after 15 minutes dose can be repeated. Subsequent dose recommendations over 24 hours have varied from 0.1 mmol/kg/hour to a total dose of 60 mmol.
- *SVT prophylaxis following cardiac surgery:* 20–25 mmol per day for 4 days.
- *Transient ventricular arrhythmia:* 10 mmol as a slow IV push, repeated if required.

- *LIMIT-2 post-myocardial infarction dose:* 8 mmol bolus over 5 minutes, followed by 65 mmol over 24 hours. Mean plasma level 1.55 (sd 0.44) mmol/L.[73]

Plasma Levels

Observational data would suggest that plasma levels of magnesium required for potent antiarrhythmic action are at least 1.8 mmol/L.

Adverse Effects

- When administered too rapidly, magnesium can cause hypotension by excessive peripheral vasodilatation; this is associated with an unpleasant hot-flush sensation.
- Prolonged administration or excessive dosing can produce plasma levels associated with skeletal muscle weakness, which can be clinically significant in acute-on-chronic respiratory failure.
- Excessive action can be seen if magnesium is used in the setting of hyperkalaemia, resulting in bradyarrhythmia and heart block.

Procainamide

Procainamide is a class IA antiarrhythmic drug with potent Na^+ channel-blocking activity and intermediate K^+ channel-blocking activity. The Na^+ channel-blocking action has an intermediate time constant of recovery. Procainamide has similar electrophysiological and ECG effects to quinidine but lacks vagolytic and alpha-adrenergic blocking activity:

- decreases automaticity
- increases refractory period
- slows conduction.

Procainamide is metabolised to *N* -acetyl procainamide. *N* -acetyl procainamide lacks Na^+ channel-blocking activity but is equipotent in K^+ channel blockade and prolongation of AP. The increasing effect of greater refractoriness and QT prolongation with chronic procainamide therapy relates to increased contribution of *N* -acetyl procainamide.

Clinical Use

Procainamide is used to treat both atrial and ventricular arrhythmias.

- Intravenous procainamide is more effective than lidocaine for terminating VT.
- Procainamide controls ventricular rate in AF and Afl.
- It is effective for conversion of AVNRT, AVRT and possibly AF and Afl.
- It controls rapid ventricular rate owing to accessory pathway conduction in pre-excitation syndromes and for wide-complex tachycardia that cannot be distinguished as being SVT or VT.

The need to infuse slowly to avoid hypotension is the major barrier to wider use in life-threatening arrhythmia. Maintenance therapy with procainamide is not widely used due to its side-effect profile:

- *Loading dose IV:* 15 to 18 mg/kg at 20 mg/minute until there is arrhythmia control, hypotension ensues or QRS duration increases by more than 50%. Up to 50 mg/min has been used in urgent situations.
- *Maintenance dose IV:* 1–4 mg/minute. Reduce maintenance dose by 30%–60% for moderate to severe renal or cardiac impairment.
- *Plasma levels: N* -acetyl procainamide has a longer duration of action.
- *Adverse effects:* as with quinidine, the ventricular response may be accelerated if given for SVT; QT-interval prolongation and torsade de pointes may also occur.

A reversible lupus-like syndrome develops in 20%–30% of patients receiving procainamide long term. Other side effects include gastrointestinal disturbances (less common than with quinidine), central nervous system manifestations and cardiac depression.

Lidocaine

Lidocaine, long considered an important antiarrhythmic drug for ventricular tachyarrhythmia, is now relegated to lower-choice options or missing from most treatment algorithms. Na^+ channel-blocking effect is increased in myocardial ischaemia and is unproven outside acute ischaemia settings. It has no effect on SA node automaticity, but it depresses automaticity in other pacemaker tissues. Normally, lidocaine has little or no effect on conduction. The ECG shows no changes in sinus rate, PR interval, QRS width or QT interval with lidocaine.

Clinical Use

Lidocaine has reducing importance.

- It is ineffective against SVT.
- Amiodarone has taken over as the antiarrhythmic of choice for DC shock-resistant VF.[66], [67]
- Lidocaine increases the current required for defibrillation, increases the likelihood of post-DC shock asystole and therefore is detrimental during an episode of VF.
- Prophylaxis to prevent VF in AMI can no longer be recommended.

Extensive first-pass hepatic metabolism precludes oral use of lidocaine; IV dose should be reduced by 30%–50% in severe liver disease or heart failure. The distribution half-life is about 8 minutes, and the elimination half-life is 1.5 hours in normal patients (but may be increased to >10 hours in severe heart failure or shock). An initial bolus of IV lidocaine 50–100 mg (0.7–1.4 mg/kg) over 1–2 minutes. A further dose may be repeated if initial is ineffectual. Thereafter an infusion of 4 mg/min for 1 hour, then 2 mg/min for 2 hours, and thereafter 1–2 mg/min, is recommended. Increasing the maintenance infusion rate without an additional bolus requires about 6 hours (four elimination half-lives) to reach a steady state. If the initial bolus is ineffective, another bolus of 1 mg/kg may be given after 5 minutes. Another dosage regimen is 0.7–1.4 mg/kg initially, and 0.8 mg/kg at 8-minute intervals for three doses (i.e. three distribution half-lives), and thereafter 1–2 mg/min by infusion. The half-life of lidocaine increases after

24–48 hours as the drug in effect inhibits its own hepatic metabolism and dose reduction is required.

Adverse Effects

Central nervous system toxicity with high plasma concentrations is the most common adverse effect (e.g. dizziness, paraesthesia, confusion, coma and convulsions). Uncommonly, AV block or cardiac depression may occur. Cimetidine reduces lidocaine clearance, potentially causing toxic drug concentrations.

Flecainide

Flecainide exhibits rate-dependent Na$^+$ channel blockade with slow-time constant of recovery, with marked slowing of conduction in all cardiac tissue, and little prolongation of refractoriness.

Clinical Use

- May revert AVNRT and AVRT, although adenosine and verapamil are more widely used
- Useful in SVT, including AF and possibly Afl, particularly in the setting of accessory pathway syndromes
- Flecainide has been given in life-threatening VT.

Flecainide can be administered IV or orally. If flecainide is deemed necessary for prophylaxis of ventricular arrhythmias, therapy should start with ECG monitoring. In CAST, suppression of VEBs after myocardial infarction with flecainide was associated with increased mortality:

- *Dose:* IV loading 2 mg/kg at 10 mg/min
- *Oral maintenance:* 50–150 mg 12-hourly.

Adverse Effects

- Depression of cardiac contractility – flecainide is usually contraindicated in patients with abnormal LV function as it can worsen or precipitate heart failure.

- Conduction block – avoid high-degree AV block unless a pacemaker is in situ.
- Flecainide increases pacing capture threshold.
- Proarrhythmic events are common, especially in patients with depressed LV function, and may be life threatening.
- Torsade de pointes may occur, even in patients without structural heart disease.
- Incessant VT may be induced, unresponsive to any therapy, including cardioversion.
- Although flecainide depresses intracardiac conduction, a paradoxical increase in ventricular rate may occur with Afl or AF.
- Central nervous system effects include visual disturbances, dizziness and nausea.

Propafenone

Propafenone is a class IC agent and has a structure similar to flecainide. The electrophysiological, haemodynamic and side-effect profile is also similar to flecainide and encainide. The I_{Na} -blocking profile of propafenone has a fast time constant resulting in greater activity at faster rates and less risk of bradycardia. In addition, propafenone has non-selective beta-blocking properties and can produce bronchoconstriction. Similar to flecainide, propafenone could be considered in both ventricular and SVT arrhythmia in the setting of normal LV function. Use of long-term propafenone should probably be limited because of its class IC profile, even though it was not included in the CAST study and is contraindicated in structural heart disease because of proarrhythmia.

Propafenone is metabolised by the liver and the rate can vary significantly between patients. The short terminal half-life requires at least t.i.d. administration.

- *Dose:* Conversion of AF to SR, IV 2 mg/kg over 10 minutes, oral dose 150–600 mg stat. Oral maintenance dose 150 mg t.i.d. immediate release tablets or 225 mg b.i.d. for slow release.

Amiodarone

Amiodarone is a potent antiarrhythmic agent with a complex electrophysiological and pharmacological profile. The appealing broad spectrum and haemodynamic stability of amiodarone have resulted in it emerging as the most frequently used antiarrhythmic in critically ill patients. In this setting, short-term use predominates and the formidable side-effect profile is much less significant. Amiodarone:

- prolongs AP duration.
- increases the refractoriness of all cardiac tissue.
- has Na^+ channel blockade (class I), antiadrenergic (class II), calcium channel blockade (class IV) and antifibrillatory effects. The Na^+ channel blockade of amiodarone has a fast time constant for recovery.
- QT prolongation reflects a global prolongation of repolarisation and is closely associated with its antiarrhythmic effects.

When given IV, amiodarone has little immediate class III effect: the major action is on the AV node, causing a delay in intranodal conduction and a prolongation of refractoriness. This probably explains why IV amiodarone controls the ventricular rate in recent-onset AF but is less effective for termination of this arrhythmia. Administration IV causes some cardiac depression, the magnitude depending on rate of administration and pre-existing LV function. Cardiac index is often unchanged because of its vasodilator properties.

Clinical Use

It is effective in suppressing both supraventricular and ventricular tachyarrhythmia.

Supraventricular Tachycardia

Amiodarone is effective in terminating and suppressing recurrences of AVNRT and AVRT tachycardia, although adenosine (for acute reversion) or verapamil (acute termination and long-term prophylaxis) is superior. Amiodarone IV is less effective in reverting Afl or AF, but the ventricular rate will slow. Administration over a longer time span (days to weeks) may be more effective in reverting recent-onset AF. In preventing recurrence of AF after reversion, amiodarone is comparable in efficacy to quinidine and flecainide but superior to sotalol and propafenone. [44]

Dose

- Lower doses than that required for ventricular arrhythmia are usually sufficient
- *AVNRT and AVRT reversion or AF and Afl rate control:* 5–7 mg/kg over 30–60 minutes depending on blood pressure and myocardial function. Alternatively, for an adult, 150 mg over 10 minutes followed by 0.5–1.0 mg/minute up to a maximum of 1.2–1.8 g per 24 hours. Poor rate control can be improved with additional 1–2 mg/kg boluses
- *Postoperative AF prophylaxis:* 200 mg orally 8-hourly for 5 days, followed by daily until hospital discharge
- *Long-term SVT control or AF rate control:* 100–200 mg/day orally will usually suffice.

Ventricular Tachyarrhythmias

Amiodarone IV may be effective in treating life-threatening ventricular tachyarrhythmia refractory to other drugs, especially in myocardial infarction and poor LV function. Amiodarone's efficacy in DC shock-resistant VF further confirms a prominent role in this setting. [66], [67] Long-term oral amiodarone is useful in controlling symptomatic VT and VF, especially when other conventional antiarrhythmics have failed. The absence of negative inotropic effect is useful in those with severely depressed LV function, but its many adverse effects limit widespread use. The Cardiac Arrest in Seattle, Conventional versus Amiodarone Drug Evaluation (CASCADE) study demonstrated that empirical amiodarone treatment was superior to guided (non-invasive Holter or EPS) class I drugs in survivors of VF not associated with AMI. Amiodarone prevented arrhythmia recurrence and decreased the incidence of sudden death. Amiodarone, presumably because it is better tolerated in patients with poor

LV function and having less proarrhythmia, can be considered as first-line drug to prevent life-threatening ventricular tachyarrhythmias.[78–80] The rate of arrhythmia control is often slower with ventricular arrhythmia and may take several days to achieve. This delay appears to be independent of dose. The pharmacodynamic basis for this relates to the fact that much of the class III or K^+ channel-blocking activity is due to the amiodarone metabolite, desethylamiodarone, whereas the predominant actions of acute administration of amiodarone are due to its class I and class II activity. The full potency of the class III activity requires several days, at least, for the effects of desethylamiodarone to appear.

Dose

- *Haemodynamically stable VT:* 5–7 mg/kg over 30–60 minutes, followed by 0.5–1.0/minute.
- *DC shock-resistant VF:* 5 mg/kg, followed by 2.5 mg/kg if required.[65]
- *Long-term prevention of ventricular arrhythmia:* oral loading with 1200 mg/day for 1–2 weeks, reducing to 400–600 mg/day and then 100–400 mg/day after 2–3 months. The dose should probably not be reduced below 400 mg/day with life-threatening ventricular arrhythmia.

Myocardial Infarction

Data are limited at present, but amiodarone may improve long-term survival in patients after myocardial infarction.

Pharmacokinetics

Oral bioavailability of amiodarone is variable at 40%–70%, with a delayed onset of action (days to weeks); however, loading doses reduce this interval. The kinetics of amiodarone have been modelled to four compartments when given acutely. Following a slow IV bolus over 15 minutes, amiodarone is rapidly distributed to the active compartment ($t_{1/2}\alpha = 4.2$ minutes), with demonstrable prolongation of QTc and antiarrhythmic effect within 2–5 minutes. Subsequently, amiodarone is progressively redistributed to ‘deeper’ compartments ($t_{1/2}\beta = 36.6$ minutes, $t_{1/2}\gamma = 4.5$ hours and $t_{1/2}\delta = 33.6$ hours).[103] This is in contrast to the very prolonged terminal half-life – greater than 50 days – after long-term treatment. This redistribution of amiodarone explains why repeated boluses are often required in the first 24–48 hours of treatment. Transient loading-dose hypotension due to myocardial depression or vasodilatation is dose-, rate- and patient-dependent. A loading dose of 5 mg/kg over 20 minutes resulted in significant further myocardial depression and a fall in cardiac index, whereas in patients without evidence of heart failure, 5 mg/kg over 1 minute resulted in hypotension due to systemic vasodilatation and an increase in cardiac index.[104], [105]

Monitoring

Plasma amiodarone concentrations have poor correlation with arrhythmia control, and therapeutic levels, 1.0–2.5 mg/L, have the greatest utility for avoidance of adverse effects in long-term treatment.

Adverse Effects

Adverse effects will occur in the majority of patients if they receive amiodarone for long enough. Most are reversible when the drug is discontinued. Adverse effects include:

- *Dermatological:* photosensitivity, bluish/grey skin discolouration (slate-blue skin)
- *Eye:* corneal microdeposits (almost 100%) with little or no clinical significance
- *Gastrointestinal disturbances*
- *Hypo- and hyperthyroidism*
- *Liver dysfunction:* asymptomatic increases in liver enzymes are common, and do not require amiodarone cessation unless enzymes are 2–3 times normal; hepatitis is rare
- *Neuropathy, myopathy and cerebellar abnormalities*
- *Pulmonary toxicity:* unexpected acute respiratory distress syndrome has been reported in patients on amiodarone undergoing procedures such as uncomplicated cardiopulmonary bypass surgery

and pulmonary angiography. These observations suggest that amiodarone may predispose the lung to acute injury. Pulmonary toxicity is the most serious adverse effect, with a reported incidence of 10% at 3 years. Amiodarone pulmonary toxicity has been reported in one case after 13 days and 11.2 g cumulative dose and 11.2 g over 2 weeks in another. Patients on long-term amiodarone need regular respiratory function testing and decreased carbon monoxide diffusion of 15% below baseline requires dose modification or cessation. The severe syndrome of shortness of breath, cough and fever with pulmonary crepitations and widespread pulmonary infiltrates on chest X-ray has a mortality of 10%. Immediate discontinuation is necessary. Use of steroids is controversial.

Amiodarone interacts with other drugs, potentiating warfarin, digoxin and other antiarrhythmic agents. When administered concurrently, doses of these drugs should be reduced accordingly. On the positive side, long-term amiodarone is unlikely to precipitate or worsen heart failure and proarrhythmia is uncommon.

Dronedarone [46, 106]

Dronedarone is an amiodarone analogue designed to reduce the lipophilicity of the molecule to reduce the pharmacokinetic complexity and toxicity. The iodine moieties have also been eliminated to prevent thyroid dysfunction.

Dronedarone is a multi-channel blocker, blocking I_{Na}, I_K and $I_{Ca\text{-}L}$ channels with a predominant electrophysiological effect of prolonging repolarisation or class III. It also has antiadrenergic properties.

Dronedarone decreases the recurrence of AF, controls rate with recurrences (heart reduction of 12.3 beats/min compared with placebo), especially with exercise. Sequential major studies evaluating dronedarone highlight the importance of variable outcomes in differing patient populations. In comparing dronedarone with placebo, the ATHENA study found dronedarone reduced all-cause mortality, cardiovascular admissions by 24%, death from cardiac arrhythmias, HR 0.55 (0.34–0.88) and stroke rate in addition to delaying recurrence of AF/Afl. Whereas in the PALLAS study (patients with permanent AF), all these outcomes were worse and the ANDROMEDA study (patients with poor LV function) was stopped due to increased mortality due to worsening heart failure. Meta-analysis of all placebo-controlled trials does show dronedarone has reduced mortality, but maintenance of sinus rhythm and absence of LV dysfunction is important to confer this mortality benefit. Dronedarone is currently contraindicated in patients with New York Heart Association (NYHA) class III or IV heart failure.

In comparing dronedarone to amiodarone, the picture is even less clear. In the DIONYSOS study (post electrical cardioversion) there was increased AF recurrence, dronedarone 63.5% and amiodarone 42% at 7 months, although drug discontinuation was higher with amiodarone. Meta-analysis of studies comparing the two drugs confirms greater efficacy for amiodarone maintaining sinus rhythm (HR 0.49; 0.37–0.63) but greater drug discontinuation rates and a trend to increased all-cause mortality with amiodarone. Dronedarone may have reduced torsade de pointes arrhythmia. The increased efficacy of amiodarone may relate to its lipophilicity giving higher tissue levels or the increased activity of its major metabolite, desethylamiodarone compared with *N* -debutyldronedarone.

Dronedarone has poor oral bioavailability, 15%, which can be variable, increasing by a factor of three if taken with food. It is extensively metabolised by cytochrome P450 CYP3A4 (inhibitors can result in marked elevation in plasma levels) to the metabolite *N* -debutyldronedarone, which is much less potent. The elimination half-life is 24 hours. Serum digoxin levels are increased due to inhibition of P-glycoprotein-mediated intestinal and renal excretion.

- *Dose:* 400 mg oral b.d. with steady state in 7 days.

Although long-term data are lacking, there has been no evidence of thyroid dysfunction or pulmonary toxicity.

Sotalol

Sotalol prolongs AP duration, thereby prolonging the effective refractory period in the atria, ventricles, AV node and accessory AV pathways. It is also a potent non-cardio-selective beta-adrenergic blocker (class II). Sotalol also has antifibrillatory actions that are superior to those of conventional beta blockers. It can worsen heart failure in patients with depressed LV function. The negative inotropic beta-blocking effect is slightly offset by a weak positive inotropic effect owing to prolongation of the AP (resulting in more time for calcium influx into contracting myocardial cells).

Clinical Use

Higher doses of sotalol are required to prolong cardiac repolarisation than to cause beta blockade. Sotalol may be administered IV or orally, and is excreted by the kidneys (elimination half-life 15 hours); Should only be used if QTc is less than 450 ms. If QTc increases to greater than 500 ms during treatment, dose should be reduced or ceased. IV dose is 75 mg (0.5–1.5 mg/kg) over 5 hours. C_{max} for 75 mg IV over 5 hours equivalent to 80 mg oral. Oral therapy is initiated at 80 mg 12-hourly and increased to 160 mg 12-hourly, although doses of 320 mg 12-hourly have been administered. Maintenance dosing is dependent on renal function. If CrCl is less than 40 mL/minute long-term sotalol is contraindicated, 40–60 mL/min once-daily dosing and greater than 60 mL/min b.i.d. dosing.

Supraventricular Tachycardia

- Effective in AVNRT and AVRT, although adenosine and verapamil are superior. Long-term sotalol will prevent recurrences of these arrhythmias.
- Probably ineffective for reversion of AF/Afl, but is effective in preventing recurrence of AF after cardioversion. If AF recurs, heart rate is likely to be well controlled with sotalol.
- Prevents postoperative SVT.

Ventricular Arrhythmias

Sotalol is superior to lidocaine to terminate sustained VT and should be considered a first-line drug in patients without heart failure. Oral sotalol is more effective than class I drugs for the long-term prevention of VT or VF. Guided (Holter or EPS) sotalol and empirical amiodarone are first-line drugs to prevent recurrences of VT and VF over the long term; however, the worse outcome with sotalol in SWORD has significantly reduced the role of sotalol in this setting. [77]

Adverse Effects

Side effects of sotalol are mainly due to beta blockade (e.g. bronchospasm, heart failure or AV conduction problems) and prolongation of QT proarrhythmia (e.g. torsade de pointes, similar 2% incidence as quinidine, which may occur early during drug titration or later during long-term treatment).

Ibutilide

Ibutilide is an I_{Kr} K^+ channel blocker, which prolongs AP and increases the refractory period. This agent, with class III effect, is recommended for acute pharmacological conversion of AF and Afl, or as an adjunct to improve success of DC shock cardioversion. The success rate for ibutilide alone is higher for Afl (50%–70%) than that with AF (30%–50%) and, as expected, efficacy is greatest in short-term AF/Afl without structural heart disease. The major role of ibutilide appears to be cardioversion pretreatment to facilitate reversion to sinus rhythm from AF. [48] Ibutilide has minimal effect on blood pressure and heart rate and the major adverse effect is proarrhythmia, with torsade de pointes occurring in 3%–6% of patients. For this reason, patients should be monitored for at least 6 hours after administration. Ibutilide has a short duration of action and other antiarrhythmic drugs are required to maintain sinus rhythm.

Dose

For patients weighing more than 60 kg, 1 mg over 10 minutes, which can be repeated 10 minutes later if unsuccessful. In patients weighing less than 60 kg, 0.01 mg/kg is given as initial dose.

Dofetilide

Dofetilide is one of the latest class III I_{Kr} K^+ channel blockers being investigated in the hope of finding an antiarrhythmic drug for long-term use with amiodarone's efficacy but without its side-effect profile. Dofetilide's emerging role is again in pharmacological cardioversion of AF and Afl (superior to sotalol, similar to amiodarone but inferior to ibutilide) in about 30% of patients. Prevention of recurrence is similar to amiodarone and long-term oral therapy is not associated with increased mortality in post-MI and heart failure patients. It also appears safe in patients with LV dysfunction. Early (first 3 days) proarrhythmia (3.3% of patients developed torsade de pointes) also necessitates monitoring with commencement of therapy.[44], [107-109]

Dose

Recommended dose is 500 µg orally 12-hourly. Dose requires adjustment for renal function and QT-interval monitoring for a minimum of 3 days. First dose is based on renal function. CrCl less than 20 mL/minute dofetilide is contraindicated. CrCl 20–40 mL/minute, 125 µg b.i.d., 40–60, 250 µg b.i.d. and greater than 60,500 µg b.i.d. Second dose is based on QTc increase. QTc increase less than 15% continue same dose. Increase greater than 15% dose is decreased. QTc interval greater than 500 ms necessitates cessation.

Vernakalant[110]

Vernakalant, a pyrrolidine compound, is a new multi-channel blocker with I_K - and I_{Na} -blocking activity, with I_K blockade predominating (class III agent). The unique profile of vernakalant I_K blockade is the relative specificity for the atria and minimal effect on the ventricle. This specificity relates to differential activity on the various I_K -channel isoforms, with I_{Kur} blockade being much greater compared with the modest activity at I_{Kr} channels. I_{Kur} channels are the 'ultra-rapid' I_K -channels confined to the atria that are responsible for the fast early phase of repolarisation that results in the shorter AP of atrial cells. Vernakalant therefore specifically prolongs atrial refractory period and slows atrial conduction with a rate-dependent profile.

Vernakalant in non-surgical, short-duration AF (ACT I and ACT III studies, duration less than 7 days) achieved sinus rhythm in 51.7% and 51.2% (placebo 4 and 3.6%) within 90 minutes, generally less than 10 minutes (median time to conversion 10 and 11 minutes). The IV dose of 3 mg/kg over 10 minutes, followed by a further 2 mg/kg over 10 minutes if conversion did not occur within 15 minutes of the first dose, produced not only rapid but durable conversion with 99% of responders remaining in sinus rhythm at 24 hours. Vernakalant was not effective in Afl, with a conversion rate of only 7%.

A similar cohort (AVRO study) comparing vernakalant (same dose as ACT I and III) with amiodarone (5 mg/kg over 1 hour followed by 50 mg over the next hour), again in recent-onset AF, found vernakalant again superior at 90 minutes with a conversion rate of 51.7 versus 5.2%. However, at 4 hours amiodarone was catching up with 21.6% versus 54.4% conversion, with amiodarone recognised to have a longer onset of action.

In post-cardiac surgical patients who developed AF, having been in sinus rhythm preoperatively (ACT II study), vernakalant was superior to placebo with rapid conversion rates (47% vs. 14%) and times (median time 12.4 minutes). However, unlike non-surgical patients, in this cohort responders were less durable with only 60% remaining in sinus rhythm at 24 hours. In all studies, vernakalant had no effect on success rates with subsequent attempts at electrical cardioversion.

Vernakalant is extensively metabolised by the liver and subsequently excreted in the urine. The acute kinetics of vernakalant are not affected by congestive cardiac failure, renal or hepatic impairment.

Vernakalant is well tolerated with serious side effects of hypotension and bradycardia during infusion infrequent (7.6%, placebo 5.1%), slightly higher than the rates of hypotension with amiodarone.

Although vernakalant may be seen as agent of choice for rapid pharmacological conversion of recent onset of AF, <7 days (the greater efficacy of ibutilide is eroded by risk of polymorphous ventricular arrhythmia), the superior conversion rate over amiodarone would appear to be lost at 24 hours and beyond, with amiodarone also likely to be a better agent to control ventricular rate in non-responders with greater AV-blocking activity.

Adenosine

Adenosine stimulates specific A_1 receptors present on the surface of cardiac cells, thereby influencing adenosine-sensitive K^+ channel cyclic adenosine monophosphate production. It slows the sinus rate and prolongs AV node conduction, usually causing transient high-degree AV block. The half-life of adenosine is usually less than 2 minutes as it is taken up by red blood cells and deaminated in the plasma. This ultrashort half-life is a major advantage over other antiarrhythmic drugs. The effects of adenosine, both antiarrhythmic and haemodynamic, can be antagonised by methylxanthines, especially theophylline and caffeine. Dipyridamole, an adenosine uptake blocker, potentiates the effect of adenosine. Adenosine effects are prolonged in patients on carbamazepine and in denervated transplanted hearts.

Clinical Use

- *AVNRT and AVRT tachycardia:* adenosine is the drug of choice. Expected reversion rates exceed 90%.[26] The AV nodal-blocking actions of adenosine may unmask atrial activity (e.g. flutter waves in Afl).
- Diagnosis of a wide-complex tachycardia may be assisted by the use of adenosine.
- SVT with intraventricular conduction block will terminate with adenosine, whereas few VTs will revert. Whether adenosine should be used routinely to discriminate between VT and SVT with aberrant conduction in haemodynamically stable wide-complex tachycardia is unclear. Potential for haemodynamic collapse in VT is real and ILCOR advises against.

Adenosine will not revert AF. Ventricular rate may transiently increase when AF is associated with the WPW syndrome.

Adenosine is given as a rapid bolus through a large peripheral or central vein followed by a saline flush, at intervals less than 60 seconds. The usual dose is 6 mg, followed by 12 mg if response is ineffective. Another 18 mg can be given if the last dose was well tolerated.

Adverse Effects

Most patients experience transient side effects such as flushing, shortness of breath and chest discomfort. Adenosine should not be given to asthmatic patients as bronchospasm may result.

Ivabradine [111]

Ivabradine is an inhibitor of HCN channels responsible for the funny pacemaker current (I_f) of the sinoatrial node, reducing sinus rate with no direct effects on inotropy, lusitropy, systemic vascular resistance or blood pressure.

Clinical use

Ivabradine is approved for ongoing tachycardia in the setting of heart failure with reduced ejection fraction despite dose optimised or intolerance to beta blockade. HCN channels are not normally found in ventricular myocytes, however ventricular expression is increased in heart failure. Ivabradine may reduce ventricular ectopy in this setting. Ivabradine may also be utilised in chronic stable angina and sinus tachycardia. Ivabradine's ability to control sinus rate without impacting upon force of myocardial contraction makes it a potentially useful drug in the critical care setting.

Adverse effects

Ivabradine is generally well tolerated with most common side effects including bradycardia and phosphenes (visual phenomena which resolve upon drug cessation). It is primarily metabolised by CYP3A4, with an active metabolite. Caution should be exercised with concurrent use of enzyme inhibitors due to risk of toxicity.

Ranolazine [112]

Ranolazine inhibits cardiac sodium and potassium ion channel currents. Inhibition of the late-phase inward sodium current during depolarisation, in turn, enhances sodium-calcium exchange, reducing intracellular calcium overload which may contribute to diastolic impairment, compromised myocardial blood flow and arrhythmia. Ranolazine also inhibits the delayed rectifier potassium current (I_{Kr}) causing AP and mild QTc prolongation.

Clinical use

Ranolazine is predominantly utilised as a second-line agent in the management of chronic stable angina. It may have a role in AF prolonging the atrial refractory period and reducing atrial excitability. Ranolazine has been demonstrated to increase rates of AF cardioversion when combined with amiodarone infusion and may reduce supraventricular arrhythmia burden in the setting of NSTEMI or when combined with dronedarone.

Adverse effects

Ranolazine is generally well tolerated. Most common side effects include dizziness, constipation and peripheral oedema. Despite mild QT- interval prolongation an increased risk of torsades de pointes has not been reported. It is predominantly metabolised in the liver by CYP3A4 and its use is contraindicated with potent CYP3A4 inhibitors and in moderate hepatic and renal failure.

Direct current cardioversion [113]

DC cardioversion/defibrillation is an important treatment option in tachyarrhythmia. In addition to its emergency role in cardiac arrest from VF or VT, urgent DC cardioversion is indicated in haemodynamically unstable VT and sustained SVT that precipitate angina, heart failure or hypotension. More elective DC cardioversion is indicated in haemodynamically stable VT following a trial of antiarrhythmic drug therapy. Cardioversion is most commonly used in AF/Afl once potential precipitants have been eliminated and, again, usually after antiarrhythmic drug treatment to prevent further episodes. Digoxin toxicity is a relative contraindication to DC cardioversion, which should also be used with care in patients on digoxin.

Mechanism of Action

DC shocks need to produce a current density that depolarises a critical mass of myocardium, thereby leaving insufficient myocardium to maintain the re-entrant tachycardia and prevent recurrence. For VF and AF, the critical mass involves the entire ventricles or atria, whereas for the more organised tachyarrhythmia, VT and Afl, which involve specific re-entrant circuits, regional depolarisation in the path of their circulating wavefronts is all that is required. DC shocks also prolong the refractoriness of myocardium and this effect will contribute to the arrhythmia termination and prevention of immediate recurrence.

Electrical Energy

Even though the goal is to achieve a certain current through the entire heart, atria or a region depending on the arrhythmia, DC shocks are prescribed as energy measured in joules (J) or watt-seconds. Obviously, it would make more sense to be able to deliver a set current. This would prevent delivering inappropriately low currents in patients with high impedance and excessive current flow causing myocardial damage in patients with low impedance. Clinical studies to determine current doses are underway for defibrillation and cardioversion. The optimal current for VF using monophasic damped sinusoidal (MDS) waveform for cardioversion waveform appears to be 30–40 A. Current dosage for biphasic waveform is not available.

Current Waveform

Modern defibrillators deliver a current, the magnitude of which depends on the prescribed energy and thoracic impedance. This current can be delivered in a number of different waveforms.

MDS defibrillators deliver current that is in a single direction or polarity. They can be further characterised by the rate at which the current pulse returns to zero. MDS waveforms return to zero gradually, whereas truncated exponential waveforms return instantaneously. Biphasic waveform for cardioversion (BTE) has superseded monophasic waveforms, achieving equivalent efficacy at lower electrical energies. BTE is a sequence of two current pulses generated with the polarity of the second in the direction opposite to the first. Biphasic waveforms with lower shock energies are associated with fewer ST-segment changes and less post-resuscitation myocardial dysfunction and have an ILCOR class IIa recommendation.

Thoracic Impedance

The magnitude of the current flow is dependent on the resistance to the current flow or thoracic impedance. The average adult thoracic impedance is 70–80 Ω. Factors that determine thoracic impedance include:

- energy selection
- electrode size
- electrode composition
- paddle-to-skin coupling
- distance between electrodes
- number of previous shocks
- time interval between previous and present shock
- pressure on electrodes
- phase of ventilation
- patient’s body build
- recent sternotomy

Conductive gel reduces impedance, while hair-trapping air between skin and paddle and self-adhesive monitor/defibrillator electrode pads may increase it. There is no clear relationship between body size and energy requirements but compensation for patient-to-patient differences in impedance can be achieved by changes in duration and voltage of shocks, or by a process called burping, which involves releasing the residual membrane charge.

Paddle Position and Size

ILCOR recommends standard placement of the sternum paddle just to the right of the upper sternal border below the clavicle and the apex paddle to the left of the nipple, with the centre of the paddle in the mid-axillary line.

Permanent pacemakers and ICDs must be avoided as shock may cause malfunction or block current going to the heart. Inevitably, some current passes down the pacemaker lead and it is necessary to check pacing threshold post-shock. Other alternative paddle placements can enable avoidance of pacemakers and ICDs or perhaps improve current direction. Using self-adhesive electrodes, the sternum electrode can be placed posterior to the heart on the right infrascapular region and the apex on the left precordium. The use of right parasternal and left posterior infrascapula has been advocated for AF because this configuration provides an optimal vector of current delivery to the atria. Large electrodes or paddles have less impedance; however, excessively large electrodes may result in less transmyocardial current flow. The minimum recommended electrode size is 50 cm^2, with the sum of both electrodes exceeding 150 cm^2.

Synchronised Cardioversion

With cardioversion of atrial tachyarrhythmia and VT, when time permits, synchronisation of DC shock with the R-wave of the QRS complex is required to reduce the possibility of inducing VF by delivering the shock during the relatively refractory portion of the T-wave of the cardiac cycle. Synchronisation in VT may be difficult and misleading because of its wide complex or polymorphous nature. Synchronisation should not delay DC shock in pulseless VT or VT associated with unconsciousness, hypotension or severe pulmonary oedema.

Direct Current Shock Dosage

Recommendations for energy doses are changing, as biphasic waveform generators become more widely available. Where studied, BTE shocks have been consistently as effective as higher-energy MDS shocks. Recommended doses are always a balance between the energy likely to generate a critical current flow and that is not likely to cause functional and morphological damage. Electrical energies greater than 400 J have been reported to cause myocardial necrosis.

- *VF and pulseless VT:* BTE shock at 200 J. Evidence for sequential escalation of the energy dose is not strong and repeated shocks at the same energy result in increasing current delivery as impedance falls. Repeated non-escalating lower-energy BTE shocks, in the range of 150–175 J, are as effective as escalating MDS recommendations.
- *VT:* energy dose for cardioversion of VT depends on morphology and rate. For monomorphic VT, synchronised 100 J BTE is the starting energy. For polymorphic VT, synchronised if possible, 200 J BTE is the starting energy and for both stepwise increases if the first shock fails.
- *AF:* initial energy is synchronised 100–200 J BTE and stepwise increases if first shock fails. Despite obvious concerns for myocardial injury, mega dose energy at 720 J MDS has been used with success in large patients with AF refractory to 360 J, without evidence of myocardial injury. Constant-current, rectilinear biphasic waveforms, BTE appear to be more effective in cardioverting AF. This biphasic waveform at the low energy of 120 J was superior to 200 J MDS.
- *Afl, AVNRT and AVRT:* these atrial tachyarrhythmias require the least energy and the initial recommended energy is synchronised 50–100 J BTE.

Sedation

A separate doctor expert in managing the airway must perform sedation for cardioversion. The dose of the sedating agent is titrated on the basis of patient factors and type of arrhythmia. Patients with poor myocardial function not only need reduced dose but also onset time is slower because of low cardiac output. Sensitive tachyarrhythmias such as Afl require only low doses, whereas AF is likely to need higher and repeated doses as higher energy and repeated shocks may be necessary. Cardioversions should be performed with standard resuscitation equipment available and preoxygenation is crucial.

Digoxin and Cardioversion

Digoxin toxicity results in a significant reduction in the threshold for inducing ventricular arrhythmia with DC shock. If digoxin toxicity is a possibility, then reconsideration of the need for cardioversion or at least careful titration of energy is required. Clinical experience would suggest the latter procedure of starting with 10 J BTE, and a stepwise increase thereafter increases safety of DC shock in this setting.

Anticoagulation for Cardioversion [113]

Cardioversion of AF and, to a lesser extent, Afl is associated with catastrophic thromboembolism, especially stroke. Early studies suggested an incidence of up to 6.3% without anticoagulation. It is accepted that the likelihood of clots forming in the left atrium after 48 hours in AF and for these to be dislodged when sinus rhythm is restored is so high that anticoagulation is indicated prior to cardioversion in AF.

Anticoagulation for 3–4 weeks before cardioversion reduced the risk of embolism by 80%. The risk of thromboembolism following cardioversion continues for a period.

- Echocardiographic findings suggestive of atrial thrombi formation occur in up to 35% of patients post cardioversion.
- Left atrial appendage emptying velocities often decrease despite the development of coordinated electrical activity after cardioversion, presumably because of stunning of mechanical function.

Prolonged AF greater than 48 hours requires anticoagulation for 3 weeks prior to cardioversion and warfarin therapy for at least another 4 weeks depending on risk of recurrence of AF.

Transoesophageal echocardiography, which allows detection of thrombi in the left atrial appendage with much greater accuracy, has been found to be a safe means of expediting cardioversion. Anticoagulation with heparin for 1 day or warfarin for 5 days prior to demonstrating the left atrium to be free of thrombi by transoesophageal echocardiography, then 4 weeks of warfarin following cardioversion, was as effective in preventing emboli as the conventional longer anticoagulation regimen. However, there was a significant reduction in major haemorrhagic events in the transoesophageal echocardiography-guided, shorter lead-in anticoagulation strategy.
